Foreword

Risk means different things to different people, and even within the technical realm of statistics it has a multiplicity of meanings. Different dictionaries and encyclopedias define it differently. A common definition found in multiple places on the WWW and elsewhere is that risk is “a potential negative impact to an asset or some characteristic of value that may arise from some present process or future event”. In everyday usage, risk is often used synonymously with the probability or expectation of a (known) loss. Implicitly, for risk to exist, there must be uncertainty about a known quantity or about an event that has an unknown outcome (e.g., see the links in statistics among risk, utility, loss, and decision-making under uncertainty).

Risk plays a strong role in many of today’s most pressing problems such as the protection of privacy, bio-surveillance, and the detection and control of environmental hazards. Statistical notions are inherent in almost all aspects of risk analysis and risk assessment. The *Encyclopedia of Quantitative Risk Analysis and Assessment* brings together a diverse collection of articles dealing with many of these different perspectives of risk and its assessment. Virtually every topic from modern statistical methodology has found its way into the entries ranging from Causation and Confounding, through Bayesian Analysis and Markov Chain Monte Carlo Simulation, Randomized Controlled Trials, Social Networks, and Survival Analysis. Each is examined from the perspective of risk assessment as well as from the perspective of specific health and other hazards, such as those associated with substances such as arsenic, asbestos, and lead, as well as with global warming, ozone depletion, and water pollution. The result is a fascinating collection of articles that spans the field of statistics and its application to human affairs, including work in cognate fields such as epidemiology, ethics, finance, insurance, and the legal theory of toxic torts.

These topics and especially their application to risk assessment cannot be found in a single or even a handful of standard sources, and readers would normally need to consult multiple books and encyclopedias to gain access to authoritative descriptions of the technical topics and their relevance. The Editors of the *Encyclopedia of Quantitative Risk Analysis and Assessment* have assembled a series of entries from distinguished experts on an interlocking set of topics and it should prove to be a major reference in this domain for years to come as members of society collectively attempt to cope with the multiplicity of aspects of risk, its measurement, and its assessment.

Preface

Exposure to risk permeates our daily experiences. The assessment of risk and strategies to reduce the likelihood of suffering harm or loss is the concern of all scientific endeavors. However, the study of risk has never evolved into its own area with its own language and methodologies. Instead, risk analysis is a cross-cutting topic combining areas that might include such diverse subjects as engineering, medicine, finance theory, public policy, and the military. Independent of the specific areas of applications, the core ideas behind risk assessment and analysis are essentially the same. A solution depends upon the probabilities of the occurrence of a set of potential problems, the probabilities of different levels of catastrophes being realized if a particular problem occurs, and a loss function associated with the cost of each catastrophe. The challenge is the quantification of the probabilities and costs to specific problems for setting policies that minimize costs while maximizing benefits.

Different disciplines have met those challenges in a variety of ways. A few have explicitly built upon the large body of statistical work subsumed in probabilistic risk assessment, but most have not. Many have developed alternative strategies that are robust to specific kinds of uncertainty, or handle adversarial situations, or deal with dynamically changing action spaces such as decision making in an economic environment. These kinds of diverse settings have broadened risk analysis beyond the traditional mathematical formulations.

Currently, the relevant literature on risk assessment is scattered in professional journals and books, and is not readily accessible to those who would profit from it. The aim of the encyclopedia is to draw together these varied intellectual threads in the hope that risk analysts in one area can gain from the experience and expertise of those in other disciplines. Corporate risk assessment, for example, may learn from military solutions; the work on monitoring for adverse health events might help to inform the early detection of unsafe automobiles; and portfolio management is very likely to be relevant to public policy investments.

Quantitative risk assessment is an important growing component of the larger field of risk assessment that includes priority setting and the management of risk. The statistical theory within the encyclopedia is designed to unify the study of risk by presenting the underpinnings of risk management within the context of the special features of particular areas. Applications from such diverse areas as drug safety, investment theory, public policy applications, transportation safety, public perception of risk, epidemiological risk, national defense and security, critical infrastructure, and program management are included to illustrate this unification.

Further, the need to understand the risks of an activity has spawned new classes of mathematical techniques for hazard identification, dose-response assessment, exposure assessment, and risk characterization. These concepts are discussed in the encyclopedia and illustrated with applications that require a more general description of variability and uncertainty inherent in the risk identification process than were available in the classical statistical literature.

The need for a unifying authoritative reference work on risk assessment was recognized in 2005 by John Wiley and Sons and the editors-in-chief. The project began with the identification

of 10 major areas that have contributed to the literature of developing strategies for studying risk. For each area, a section editor was recruited with known expertise in his or her field. These categories, and the section editors, are:

1. Risk management (Tony Cox)
2. Environmental risk (Walt Piegorsch)
3. Insurance/actuarial risk (Michel Denuit)
4. Financial/credit risk (Ngai Chan)
5. Toxic substances/chemical risk (Dennis Paustenbach and Jennifer Roberts)
6. Reliability (Frank Coolen and Leslie Walls)
7. Bayesian methods/decision analysis (Simon French)
8. Clinical risk (Susan Sereika)
9. Epidemiology/public health (Susan Sereika)
10. Homeland security (Edward Melnick)

Once recruited, editors-in-chief and section editors developed a list of entries within each topic, and from there the section editors solicited authors. The entries were chosen to provide a broad coverage of methods and applications of risk quantification and analysis. Some entries were chosen to cover material at a basic level, while others were at a sophisticated mathematical level. The goal was to make the encyclopedia meet the needs of a wide readership with articles that differed in technical level and mathematical content.

The section editors did an outstanding job of soliciting leading authors to write authoritative articles on selected key topics. Out of approximately 400 potential authors, they were able to recruit all but a handful. We would like to thank all of them for their very substantive and insightful contributions.

Once the first draft of manuscripts was received, the editors-in-chief read and made suggestions to the section editors. The section editors then worked with the authors as supporters and editors. Once the section editors accepted the final version of the manuscripts, the editors-in-chief set up the cross-referencing and compiled all the articles into the encyclopedia.

Any success that the encyclopedia may have will be due, in no small measure, to the efforts of the nearly 360 authors. They all worked very hard, often through multiple drafts, to produce this work. With the editors-in-chief on different sides of the Atlantic, and section editors and authors spread all over the world, this work could not have been carried out without the Internet. We want to thank all who responded promptly to messages sent in the middle of the night (their time) or just after they went home for the weekend.

This encyclopedia uses a system of cross-referencing to make the material more accessible to the reader. Firstly, other articles that the reader might be interested in are cross-referenced using the words “see” or “see also” in parentheses at the appropriate location within the text of an article. For example, ‘...of the air pollutant in ambient air (*see* **Air Pollution Risk**)’. Secondly, related articles are listed at the end of many of the articles, under the heading “Related Articles”. Finally, there are a number of “blind entries” that refer the reader to a full-length article. For example, ‘**Polypatterns: See Remote Sensing,**’ or ‘**Epistemic Communities: See Scientific Uncertainty in Social Debates around Risk.**’

Jill Hawthorne, who was our Project Editor at Wiley, did a superb job leading us along, providing encouragement where it was needed, and somehow keeping complete track of over 300 articles in various stages of completion. We could not have done this without her. We are also grateful for the assistance offered by her colleagues at Wiley, including Daniel Finch, Layla Harden, Debbie Allen and Tony Carwardine all of whom did sterling work on the project.

We also acknowledge the contribution of Sangeetha and the team at Laserwords Private Ltd., who were responsible for the copyediting and typesetting of all the articles.

John Wiley & Sons, Ltd was supportive of this work throughout. They provided funds for several meetings of the editors-in-chief, and made much of the editorial process almost completely transparent to us.

Absolute Risk Reduction

Absolute Risk

Risk is defined in the *Shorter Oxford English Dictionary* (fifth edition, 2002) as “the possibility of incurring misfortune or loss”. Quantifying and assessing risk involve the calculation and comparison of probabilities, although most expressions of risk are compound measures that describe both the probability of harm and its severity. Americans, for example, run a risk of about 1 in 4000 of dying in an automobile accident. The probability for lethally severe injuries is 1 out of 4000.

Perceptions of risks are influenced by the way the risks are presented. You might be worried if you heard that occupational exposure (*see* **Occupational Cohort Studies**) at your job doubled your risk of serious disease compared to the risk entailed while working at some other occupation: you might be less worried if you heard that your risk had increased from one in a million to two in a million. In the first case, a relative risk is presented, in the second an absolute risk. Relative risk is generally used in medical studies investigating possible links between a risk factor and a disease – it is an extremely important index of the strength of the association between the factor and the disease (*see* **Logistic Regression**), but it has no bearing on the probability that an individual will contract the disease. This may explain why airplane pilots, who presumably have relative risks of being killed in airplane crashes that are of the order of a 1000-fold greater than the rest of us occasional flyers, can still sleep easy in their beds. They know that their absolute risk of being a victim of a crash remains extremely small.

A formal definition of *absolute risk* in the context of medicine is provided by Benichou [1];

The probability that a disease-free individual will develop a given disease over a specified time interval, given current age and individual risk factors, and in the presence of competing risks.

Absolute risk is a probability and therefore, lies between 0 and 1.

Absolute Risk Reduction

Absolute risk can be used as the basis of a measure of effective size of an intervention in a clinical trial. The

measure is called the *absolute risk reduction* (ARR), which is simply the absolute difference in outcome rates between the control and treatment groups. For example, in a clinical trial of mammography, it was found that out of 129 750 women who were invited to begin having mammograms in the late 1970s and early 1980s, 511 died of breast cancer over the next 15 years, a death rate of 0.4%. In the control group of 117 260 women who were not invited to have regular mammograms, there were 584 breast cancer deaths over the same period, a death rate of 0.5% (*see* [2]). So here the estimated ARR is 0.1%. Using the same example, the *relative risk reduction* (RRR), the proportional reduction in the relative risk amongst treated and controls, is 20%. RRR is often more impressive than ARR and the lower the event rate in the control group, the larger will be the difference between the two measures. But for the individual patient, it is ARR that often matters most.

Number Needed to Treat

Over the last 10 years or so, it has become an increasingly popular practice among clinicians to express the ARR in a way that they see as being easier for their patients to understand: one such approach is to use *number needed to treat* (NNT) which is simply the reciprocal of ARR. It gives the estimated number of patients who needed to undergo the new treatment rather than the standard one, for one additional patient to benefit. For example, in a study of the effectiveness of intensive diabetes therapy on the development and progression of neuropathy, 9.6% of patients randomized to usual care and 2.8% of patients randomized to intensive therapy suffered from neuropathy. Consequently, the ARR is 6.8% leading to an NNT of 14.7 ($= 1/6.8\%$). Rounding this figure up, the conclusion is that 15 diabetic patients need to be treated with intensive therapy to prevent one from developing neuropathy (this example comes from the web site of the Centre for Evidence Based Medicine: <http://www.cebm.net/>).

Altman [3] shows how to calculate a confidence interval for NNT, although this is not considered helpful if the 95% confidence interval for ARR includes the value zero, as this gives rise to a nonfinite confidence interval for NNT. There have been some criticisms of NNT (*see*, for example, Hutton [4]), but Altman and Deeks [5] defend the concept as a useful communications tool when presenting results from

clinical studies to patients. (The concept of NNT can equally well be applied to harmful outcomes as well as those that are beneficial, when instead it is referred to as the *number needed to harm*.)

Accelerated Life Testing

General Description of Accelerated Life Testing

Accelerated testing (*see Reliability Growth Testing; Reliability Demonstration; Reliability of Consumer Goods with “Fast Turn Around”; Reliability Integrated Engineering Using Physics of Failure*) is a set of methods intended to ensure product reliability during design and manufacturing and after product fielding. In all accelerated testing approaches, stress is applied to promote failure. The applied stresses can be environmental (e.g., temperature, humidity, vibration, shock, corrosive gasses, and electromagnetic), application loading (e.g., duty cycle and configuration), or interface loading (e.g., varying line voltage, repeated electrical connector removal and installation, and mounting base flexure). By the term accelerated, a shortened time to failure is implied. However, accelerated tests are commonly used for two very different purposes. If the intention is to use accelerated testing to predict product lifetime [1], the stress must produce the same degradation mechanism and failure types that would be encountered during the product's intended use. If the intention is to use accelerated testing for new product qualification or for manufacturing quality verification, then the stress applied may be unrelated to expected field stress.

In order to make a valid inference about the normal lifetime of the system from the accelerated data, it is necessary to know the relationship between time to failure and the applied stress. This will, of course, depend upon the nature of the system and the nature of the stress applied. Typically, a parametric statistical model of the time to failure and of the manner in which stress accelerates aging is used.

Statistical Models of Accelerated Life Testing

Analysis of accelerated life test data requires acceleration models (or stress relationship models (*see Hazard and Hazard Ratio*)) that relate time acceleration to stress variables like voltage, temperature, physical stress, and chemical environment. A statistical lifetime distribution is commonly used to model

the lifetime to failure mechanism. Frequently used distributions are lognormal, Weibull, exponential, and logistic. Published successful applications should be used as reference for initial model selection considerations. Validation of the model can only be performed after the distribution of time to failure is observed under normal (unstressed) conditions.

Life Stress Relationship Models

Arrhenius. The Arrhenius lifetime relationship (*see Comparative Risk Assessment*) is most commonly used to model product lifetime as a function of temperature. It is one of the earliest and most successful acceleration models that predict how time-to-failure changes with temperature. The Arrhenius rate law states the relationship between the rate of chemical reaction and temperature as

$$R(T) = A \exp \left[\frac{-E}{kT} \right] \quad (1)$$

where R is the chemical reaction rate and T is the temperature in absolute scale [K], k is Boltzmann's constant (8.63×10^{-5} eV K⁻¹), and E is the activation energy in electron volts (eV). The parameter A is a scaling factor determined by product or material characteristics. Activation energy, E , is a critical parameter in the model that depends on the failure mechanism and materials involved. The Arrhenius acceleration factor is given by

$$AF = \exp \left[\frac{E}{k} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \right] \quad (2)$$

where $T_2 > T_1$ (in Kelvin).

Inverse Power Law. An inverse power relationship is commonly used to model product lifetime as a function of an acceleration stress. The relationship is also called the *inverse power rule* or *inverse power law* or *simply power law*. The model can be written as

$$R(V) = AV^{-\beta} \quad (3)$$

where V is the stress.

Voltage Models. Temperature and voltage stress can be modeled with the following relationships:

$$R(V) = Ae^{\frac{E}{kT}} V^{-\beta} \quad (4)$$

$$R(V) = Ae^{\frac{E}{kT}} e^{-BV} \quad (5)$$

Outcome Variables

Failure is defined as a preset amount of degradation of a system as well as the catastrophic failure of the unit. In accelerated life testing, catastrophic failure modes such as fire and mechanical collapse are often avoided and replaced by an outcome variable passing a certain threshold. This outcome variable has to be materially linked to the final catastrophic failure mode. A few examples of this concept for accelerated life testing are as follow. For crack accelerated fatigue-crack growth, the crack reaching a specified length may be considered a failure. For fire risk, the system elevating to the autoignition temperature of the material would be defined as failure. A system where the failure may not be characterized by a measured characteristic might be death by disease.

The failure criterion variable used must be directly related to the failure mode at hand, and should be selected for both relevance and ease of measurement during testing. The failure criterion variable must be different from the acceleration variable, i.e., if the time to reach auto ignition temperature is the failure criterion, temperature cannot be the accelerating variable; another relevant variable such as current or chemical exposure must be chosen.

Once the failure criterion variable is decided on, the appropriate range of acceleration variables must be selected. This process is not trivial and must generally include a few quick experiments. The first consideration is to whether there are any natural limitations on the degree of acceleration that is possible while maintaining the same physical mechanisms. For example an accelerated thermal test cannot exceed the melting temperatures of the materials involved and still be relevant. The same would be true for glass transition temperatures in polymers and current levels that would begin to melt conductors. Once these natural limitations on acceleration are defined, it is advisable to run a short experiment with the acceleration variable just under this limit in order to define the fastest feasible accelerated time to failure. It is imperative that an accelerated failure has actually been forced before choosing the range of acceleration variables for the testing.

Once the time of the fastest feasible time to failure is established, models of acceleration can be used to design an experiment that will be expected to develop a failure within the time frame of testing, generally

between 1 day and 1 month. It is desirable to use as little acceleration as possible to develop high-fidelity results within the time period available for testing.

Once the failure criterion variable has been defined, the times to failure for the population are generally defined by one of the following methods that allow the entire population to be characterized by a single outcome variable.

Mean Time between Failure. For constant failure rate of nonrepairable components or systems, mean time between failure (MTBF) (*see Reliability Growth Testing; Imprecise Reliability; Availability and Maintainability*) is the inverse of the failure rate. For example, if a component has a failure rate of 20 failures per million hours, the MTBF would be the inverse of that failure rate.

$$MTBF = (1\,000\,000\text{ h})/(20\text{ failures}) = 50\,000\text{ h} \quad (6)$$

Percent Failed at Specified Time. Percent failed at specified time (*see Comparative Risk Assessment*) is often computed as the cumulative probability of failure. Manufacturers or product developers are often more interested in knowing percent failed at specified time rather than MTBF. For example, one may want to know what proportion of the products will fail at the end of 1, 2, or 3 years. Once a parametric model, such as lognormal or Weibull is fit, the percent of product failed at a specified time can be obtained through the model. For example, an exponential failure distribution with MTBF of $\theta = 13.58$ years would give a cumulative percent of failure of 7.1% at the end of the first year. The calculation can be written as

$$P = 1 - \exp\left(\frac{-1}{13.58}\right) = 0.071 \quad (7)$$

Time to Specified Percent Failure. Time to specified percent failure (also known as *percentile of failure*) is commonly calculated from the inverse function of a probability function. For example, the inverse function of exponential distribution is written as

$$\text{Percentile} = -\theta \ln(1 - p) \quad (8)$$

where p is the cumulative probability or percent of failure, and θ is the MTBF. When $\theta = 13.58$ years

and $p = 1\%$, the corresponding percentile is 0.14 year or 1.64 months. For specified values of the parameters, percentiles from lognormal or Weibull distributions or other time-to-failure distributions can be computed.

Regression Methods

Regression methods have become increasingly common tools for analyzing accelerated failure test data, as more statistical software packages for personal computers have made these options available to analysts in recent years. Typically, the lifetime distribution is accelerated by making a linear transformation to time to event in which the accelerating factors are independent variables in the regression. More than one accelerating factor can be used. The acceleration factors may be controlled (e.g., temperature and voltage) in the experiment, but may also include uncontrolled factors (e.g., manufacturing line, operator, and batch of raw materials). Regression methods allow us to build lifetime models to account these factors and make failure predictions properly using more information. Regression methods are generally classified into two approaches: parametric models and the proportional hazards model.

Parametric. In these models, the lifetime distribution under normal operating conditions (unaccelerated) is assumed to follow a parametric distribution. Typical lifetime regression software [2] will support Weibull, lognormal, and other common lifetime distributions.

If T_0 is the time to failure under normal operating conditions, and $\mathbf{X}$ is a vector of factors that accelerate the time to failure and $\boldsymbol{\beta}$ is a vector of unknown coefficients, then the accelerated lifetime model is conveniently specified as $\Pr\{T > t|\mathbf{X}\} = \Pr\{T_0 > \exp(-\mathbf{X}'\boldsymbol{\beta})t\}$. In other words, conditional upon the values of the acceleration variables $\mathbf{X}$, $T = \exp(\mathbf{X}'\boldsymbol{\beta})T_0$. This model will allow multiple acceleration variables, e.g., stress and temperature and their interaction. The model formulation is quite general; covariates to describe differences in device design or differences in manufacturer can be added to the model.

Proportional Hazards. The proportional hazards model or Cox proportional hazards regression model

(see **Lifetime Models and Risk Assessment; Competing Risks**) is widely used in biomedical applications and especially in the analysis of clinical trial data. The model can also be used as an accelerated life testing model. The model does not assume a form for the distribution, because the form of hazard function is unspecified. It cannot be used to extrapolate lifetime in the time scale. This limits the model's ability to make early or late lifetime prediction beyond the range of the data. However, it can extrapolate lifetime in stress. The distribution-free feature makes it attractive when other parametric distributions fail to model the data adequately [3].

Bayesian Methods for Accelerated Life Testing

Meeker and Escobar [4] provide an interesting example of the use of Bayesian methods in accelerated life testing (see **Mathematics of Risk and Reliability: A Select History**) using the Arrhenius model of accelerated lifetime. When activation energy is estimated from the experimental data, the confidence bounds on the estimated distribution of time to failure are generally much larger than the case when the activation energy is known. Bayesian analysis provides a useful middle ground. A prior distribution for the activation energy is provided, and the usual Bayesian mechanics are applied. Even a diffuse prior distribution over a finite range will produce tighter confidence bounds than non-Bayesian methods with no assumption about the activation energy.

History of Accelerated Life Testing

Since accelerated testing is expensive, a cost-benefit justification is often required [5]. Justification of reliability work is not new. In 1959, US Air Force Major General William Thurman's presentation about cold war ballistic missile reliability said that some people at that time felt that "reliability was a bunch of hokum and that the Air Force was making a fetish out of it". The general provided a useful operative definition of reliability, as "the probability that the product or system will perform its required action under operational conditions for a given period of time" [6]. In 1959, General Thurman was concerned about achieving 99% reliability of an intercontinental ballistic missile, but today there are nonmilitary products such as medical products and data centers that require

even higher reliability than what General Thurman required. Although products such as consumer entertainment products do not inherently require high reliability, warranty costs often drive large investments in reliability. Technology has progressed since 1959, but designing an accelerated testing program as part of an overall reliability program still faces challenges similar to those outlined by General Thurman in 1959.

Reliability and Quality

Reliability can be briefly summarized for the purpose of the discussion of accelerated testing. Throughout the history of accelerated testing, two fundamentally different top-level approaches to reliability prediction and management for complex systems have developed. One approach divides product lifetime into three curves forming “the bathtub curve” (see **Burn-in Testing: Its Quantification and Applications**), a curve with the product’s early failure rate dropping to a steady level followed by a rapid rise. The life phases in the bathtub curve are “infant mortality”, a “useful lifetime”, and “wear out”. Much of the reliability program emphasis is placed on understanding where these phases begin and end in the product lifetime. Strategies are applied to each phase. The typical goal is to run through infant mortality in the factory using screening methods such as burn-in. The useful life phase is assumed to be governed by the exponential distribution, with a constant called the *hazard rate*, the inverse of MTBF, to predict the number of failures in the field. Finally, field data is monitored to determine when wear out begins. This approach to reliability is fundamentally different from an approach based on a combination of physical testing and modeling sometimes referred to as the *physics of failure (PoF)* (see **Stress Screening**) in which lifetime is described by a deterministic model plus a stochastic term [7]. The two approaches to reliability need not be viewed as being in conflict, as long as each is applied conscientiously, but accelerated testing definitely fits into the PoF point of view.

Economic Issues

Reliability practitioners have invented many approaches to accelerated testing [8] because of the large economic impact. Each of the popular accelerated testing approaches for consumer and business products offers a trade-off between accuracy

and cost, and some approaches target different parts of the product life cycle. However, most popular accelerated practices do not apply well to industries with rugged products, such as the petroleum and avionics industries. In any case, testing can include physical testing, such as temperature cycling, and “virtual testing” using mathematical simulation.

A priori knowledge of the expected failure mechanism is required in the design of an effective accelerated life testing plan. One way to look at failure mechanisms is to assign failures to one of the two basic classes: overstress or wear out mechanisms. With the exception of highly accelerated life testing (HALT) (see **Product Risk Management: Testing and Warranties**), accelerated life testing focuses on wear out failure mechanisms. (HALT is a design procedure defined by some proponents [9] as a test-analyze-fix-test (TAFT) (see **Reliability Growth Testing**) strategy and by Munikoti and Dhar [10] and Donahoe [11] as simply an extreme accelerated test).

Although there are a finite number of failure mechanisms, the list of failure mechanisms is long. Some of these failure mechanisms include vibration-driven loosening of mechanical fasteners, damaging flexure of components due to mechanical shock, wear of items such as electrical connectors from repeated operation, wear of mechanical bearings, shorting due to voltage-driven conductive filament formation or dendrite growth in printed wiring boards (PWBs), electric arcing due to rarefied atmosphere at altitude, electrostatic discharge, solder fatigue due to temperature cycling, fretting corrosion of electrical connectors due to normal temperature cycling, loss of volatile constituents over time and temperature in lubricants and interfaces, delamination of plastic built-up parts due to swelling from high humidity, and ultraviolet damage. Therefore, the following paragraphs provide some examples of how accelerated testing by stressing improves understanding of some types of underlying failure mechanisms.

Examples of Accelerated Life Testing

Temperature Cycling – Printed Wiring Boards

Temperature cycling is a common accelerated test used for PWBs. The primary failure mechanism in PWBs is driven by the large mismatch of coefficients of thermal expansion between the PWB base material

(e.g., a glass-epoxy laminate) [12] and either the solder (typically tin–lead or tin–silver–copper solder) used to attach electrical components or ceramic components. Given the geometry of a PWB layout and the components selected, it is possible to predict the fatigue life of solder joints. Therefore, it is possible to use greater temperature excursion while cycling to accelerate the time to solder joint failure. However, solder is near its melt temperature during specified operational temperatures (and even closer to melting during accelerated testing). As a result, analysis is difficult owing to creep and nonlinear solder material properties. Furthermore, a PWB typically has hundreds to thousands of components with many differing geometries. This example of the design of an accelerated test using only temperature cycling for a PWB shows how test design and interpretation of results can be confounding. As a result, industry has produced standard test profiles.

Separable Electrical Connectors – Insertion–Removal Cycles

Estimating the lifetime of a separable electrical connector in a consumer product is another practical example of accelerated testing. In a personal computer, for example, there are a number of electrical devices that the user plugs in and removes over the lifetime. Devices include parts inside the computer chassis such as daughter boards (e.g., graphics cards or memory modules) and external parts such as Personal Computer Memory Card International Association (PCMCIA) cards (and their progeny), the printer connector, the display connector, the mouse connector, Universal Serial Bus devices (USB), etc. During lifetime, separable electrical connectors typically suffer added electrical resistance as mechanical plating wears and the electrical circuit has a threshold electrical resistance beyond which the system will stop performing. In all of these examples, the accelerated test challenge is to determine how many insertion–removal cycles are required in product life, i.e., how many insertion–removal cycles should be tested. Also, as the connector wears, there is a concern whether environmental corrosion will damage the electrical interface during its lifetime.

Mixed Flowing Gas – Accelerated Corrosion

Mixed flowing gas (MFG) is an example of an accelerated test for corrosion due to common atmospheric

gasses. The MFG test combines several gasses with humidity to generate corrosion on common metals. Although there is some dispute about the correct acceleration factor, the test is in widespread use today. Recent applications include studies to determine the robustness of materials used to replace those substances prohibited by the European Union Restriction of Hazardous Substances Regulation [13]. The development of the test is primarily attributed to W. Abbott at Battelle Labs and to IBM [14]. A number of the major standards bodies describe the method.

Limitations of Temperature Acceleration for Mature Products

Static temperature testing is especially important for products based on digital microelectronics. Semiconductor devices are temperature dependent by their nature. Continuing miniaturization of the integrated circuit along Moore’s Law [15] has created a cooling problem [16–18]. Therefore, thermal design of modern electronics pushes limits, and, as a result, accelerated testing has little thermal headroom (the difference between the design temperature and the temperature at which the component ceases to operate or is irreversibly damaged). The thermal strategy often used today is throttling, a reduction in power consumption during normal operation. However, users may select higher operational settings that challenge the design margins. As a result, creating an accelerated test by simply increasing the ambient temperature, as was common practice, will result in the product shutting itself off. In these cases, reliability testing may be forced to working closely with the part manufacturer who, without doubt, would have performed accelerated testing during design. However, the supplier (especially if that supplier enjoys a monopoly on a particular component) may be unwilling to provide information. This puts many manufacturers into a difficult spot, as they are forced to believe unsupported reliability claims.

Highly Accelerated Stress Testing (HAST)

Highly accelerated stress testing (HAST) is a common accelerated test used for electronics (see Further Reading). HAST is described in industry standards and by test equipment manufacturers and refers to

a specific test combining temperature, pressure, and moisture. In the so-called autoclave test, the environment is the same as a household pressure cooker (121 °C, 100% relative humidity, and 2 atm [19]). Since this is an extreme condition, the test designer must ensure that extraneous failure modes are not being introduced. Examples of test issues are the temperature of material phase changes, glass transition temperatures, corrosion propensity, surface moisture due to adsorption or condensation, and changes in electrical properties. HAST is routinely used for testing hermetic integrated circuit packages, popcorning (propensity for delamination and cracking of nonhermetic integrated plastic packages due to the formation of steam within plastic voids during soldering [20]), and moisture effects in many other types of devices such as multilayer ceramic capacitors [10, 11, 21].

Actuarial Journals

Introduction

The actuarial profession consists of over 40 000 credentialed members working in over 100 countries throughout the world. In addition, there are likely to be many other professionals working in this field without formal certification. Despite the common name, there are actually various types of actuaries, whose work and interests can diverge significantly. One basic classification is life *versus* general actuaries. Life actuaries deal with life insurance, pensions, and health insurance issues; general (or nonlife) actuaries deal with property and liability insurance concerns. Another widely quoted classification was proposed by Hans Bühlmann [1] in an ASTIN Bulletin (AB) editorial published in 1987 in which he described three kinds of actuaries. Actuaries of the first kind emerged in the late 1600s and used deterministic methods to develop mortality tables and other calculations related to life insurance, and later to pension plans. Actuaries of the second kind appeared in the early 1900s and applied probabilistic methods to the developing lines of workers' compensation and automobile insurance, as well as to other property and liability insurance areas. Actuaries of the third kind, the ones who were the focus of Bühlmann's article, emerged in the 1980s to deal with investment issues for both insurers and other organizations, applying stochastic models to both assets and liabilities. Since the appearance of Bühlmann's article, a fourth kind of actuary has been identified, one who deals with enterprise risk management, the combination of all risks facing an organization, not just the insurance and financial risks on which actuaries had previously focused. Other classifications of actuaries are into lay (practical) and pure (theoretical), and into practicing and academic actuaries. The different types of actuaries, regardless of the classification system used, do have different interests, but share a common concern for advancing the profession through developing and sharing new actuarial techniques. To this end, a number of actuarial journals have been developed to stimulate research into actuarial problems and to share advances within the profession.

While there are several journals that have been very influential in actuarial science for many decades, the actuarial journal landscape has evolved over

time. A study by Colquitt [2] evaluates the relative influence that many of these journals have had in the field of actuarial science in recent years.

The Colquitt study evaluates the influence of 8 of the top actuarial science journals by reviewing the citations to each of these journals found in 16 of the top risk, insurance, and actuarial journals published in the years 1996–2000. The actuarial journals included in the study are the *AB*, the *British Actuarial Journal (BAJ)*, the *Casualty Actuarial Society Forum (CASF)*, *Insurance: Mathematics and Economics (IME)*, the *Journal of Actuarial Practice (JAP)*, the *North American Actuarial Journal (NAAJ)*, the *Proceedings of the Casualty Actuarial Society (PCAS)*, and the *Scandinavian Actuarial Journal (SAJ)*. The Colquitt study did not include all actuarial journals, only those cited in the other journals in his study. Some other leading actuarial journals include the *Australian Actuarial Journal*, *Belgian Actuarial Bulletin*, *South African Actuarial Journal*, *Bulletin of the Swiss Actuarial Association*, *German Actuarial Bulletin (Blätter of the German Actuarial Association)*, *French Actuarial Bulletin*, and *Italian Actuarial Journal (Giornale dell'Instituto Italiano degli Attuari)*. Actuarial articles also appear in many other journals, including the *Geneva Risk and Insurance Review*, the *Journal of Risk and Insurance*, and many other journals on probability or stochastic finance.

Actuarial Journal Descriptions

The *AB* (<http://www.casact.org/library/ASTIN/>) began publishing articles on general (nonlife) insurance in 1958. ASTIN, which stands for Actuarial Studies in Nonlife Insurance, is a section of the International Actuarial Association (IAA). In 1988, the *AB* began to accept a broader array of articles by including the Actuarial Approach for Financial Risks (AFIR) section of the IAA and incorporating financial risk issues. Recently, the editorial guidelines were revised to be open to papers on any area of actuarial practice. Articles published in the *AB* generally apply advanced mathematics and often are theoretical in nature. The editorial board is a combination of academic and practicing actuaries from a number of different countries so that it has an international perspective.

The *BAJ* (http://www.actuaries.org.uk/Display_Page.cgi?url=/maintained/resource_centre/baj.html)

has been published jointly by the Institute of Actuaries and the Faculty of Actuaries since 1995. Previously, each organization had its own journal, the *Journal of the Institute of Actuaries* and the *Transactions of the Faculty of Actuaries*. This refereed journal published papers on all areas of insurance research, life, pensions, and general insurance, with a focus on articles dealing with insurance issues applicable in Britain. The editorial board consists of Fellows of the Institute or Faculty of Actuaries, both practicing and academic. The goal of the *BAJ* is to provide the permanent record of advances in actuarial science. The journal includes, in addition to scientific papers, association studies and reports on meetings of the sponsoring societies. In 2007, the UK actuarial profession began a new journal, *Annals of Actuarial Science* (http://www.actuaries.org.uk/Display_Page.cgi?url=/maintained/resource_centre/annals.html) that publishes peer-reviewed articles on all aspects of insurance. The *BAJ* will continue to publish papers presented at meetings.

The Casualty Actuarial Society (CAS) publishes two journals. The *PCAS* (<http://www.casact.org/pubs/proceed/index.cfm?fa=pastind>) was the Society's refereed journal from 1914 through 2005. This journal tended to publish practical applications of actuarial research by members of the CAS, although membership was not a requirement for authors. Starting in 2007, the CAS changed the name of its refereed journal to *Variance* (<http://www.variancejournal.org/>), and actively encouraged nonmembers to submit articles. The goal of this journal is to foster and disseminate practical and theoretical research of interest to general actuaries worldwide. The other CAS journal is the *CASF* (<http://www.casact.org/pubs/forum/>). This journal is not refereed, and serves to encourage the exchange of current research. The complete texts of all papers that have been published in either the *PCAS* or the *CASF* are available at no charge through the CAS website.

IME (http://www.elsevier.com/wps/find/journaldescription.cws_home/505554/description#description), first published in 1982, is an international journal publishing articles in all areas of insurance. This journal seeks to bring together researchers in insurance, finance, or economics with practitioners interested in developing or applying new theoretical developments. The editorial board consists entirely of academics from a variety of disciplines related to

risk, including actuaries, economists, and mathematicians. The goal of this journal is to publish articles on the theory of insurance mathematics, economics, or innovative applications of theory.

The *JAP* (<http://www.absalompress.com/>), first published in 1993, aims to meet the needs of both practitioners and academics by publishing refereed articles on advanced topics of actuarial science in a format that strives to make the mathematics understandable to all readers. The editorial board includes both practicing and academic actuaries primarily from the United States. The journal publishes articles on all aspects of actuarial practice. The goal of the journal is to bridge the gap between the "art" and "science" of actuarial work on an international basis.

The *NAAJ* (<http://www.soa.org/news-and-publications/publications/journals/naaj/naaj-detail.aspx>) is the current refereed journal of the Society of Actuaries. This journal has been published since 1997 and seeks to attract both authors and readers beyond the membership of the Society. This journal publishes articles on a broad array of insurance issues, with a focus on life, health, pension, and investment topics. The editorial board consists primarily of members of the Society drawn from both academia and practicing actuaries. The Society's prior journals were the *Transactions of the Society of Actuaries*, published since 1949, and the journals of its predecessors, the *Record of the American Institute of Actuaries* (first published in 1909), and the *Transactions of the Actuarial Society of America*, published since 1891. The scientific articles published in these journals tended to be written by members, and to focus on practical applications of life, health, and pension actuarial issues. The Society of Actuaries also publishes a non-refereed journal, Actuarial Research Clearing House (ARCH), which seeks to facilitate the rapid sharing of advances within the actuarial field.

The *SAJ* (<http://www.ingentaconnect.com/content/routledge/sact>), published since 1918, is jointly sponsored by the Danish Society of Actuaries, the Actuarial Society of Finland, the Norwegian Society of Actuaries, and the Swedish Society of Actuaries, with editors from each society. This journal publishes theoretical and practical research using mathematical applications to insurance and other risk areas. This journal draws articles from authors internationally, and covers all areas of insurance.

Actuarial Journal Influence

First, the findings of the Colquitt study suggest that the journal most frequently cited by many of the citing journals is the citing journal itself. Given that the authors of articles published in a journal are obviously familiar with the journal in which the article is published, there is a resulting increase in self-citations. Another likely cause of a journal's increased self-citation rate is that a journal editor tends to appreciate an author's recognition of the influence that his/her journal has on a particular stream of literature.

Regarding the overall influence of the sample journals, *IME* was either the first or second most frequently cited journal by six of the eight actuarial journals. The only two actuarial journals where the *IME* was not the first or second most frequently cited journal were the *CASF* and the *PCAS*. In the cases of the *CASF* and the *PCAS*, the two most frequently cited journals were the *CASF* and the *PCAS*. Both of these journals are sponsored by the CAS and those who publish articles in these two journals are likely very familiar with and greatly influenced by the research published by this organization.

Colquitt also determines each journal's self-citation index. The higher the self-citation index, the higher a journal's frequency of self-citations relative to the frequency with which it is cited by the other sample journals. The lower the self-citation index, the more influential the journal is presumed to be. A relatively high self-citation index could indicate that a journal is inclined toward self-promotion or perhaps the journal publishes research on topics that are of a specialized nature and, as a result, is most frequently referenced by other articles within that same journal. Among the sample actuarial journals, the *NAAJ* (.40) has the lowest self-citation index, with *IME* (0.67), the *AB* (0.84), and the *SAJ* (0.92) following close behind. The remaining four actuarial journals and their self-citation indices are the *PCAS* (1.39), the *CASF* (1.51), the *BAJ* (1.52) and the *JAP* (5.15).

When looking at total citations, *IME* is the most frequently cited actuarial journal with 854, followed by the *AB* (658), the *PCAS* (626), the *SAJ* (453), and the *BAJ* (410). The remaining three actuarial journals were the *CASF* (194), the *NAAJ* (148), and the *JAP* (26). One reason for the low citation totals for the *NAAJ* and the *JAP* is likely the relative newness of these journals. In addition, the pedagogical nature of

some of the articles in the *JAP* and the relatively low number of *JAP* subscribers are also likely reasons for its low number of citations. When excluding self-citations, the only changes in the order is a switch in the first and second positions between *IME* (413) and the *AB* (481) and the switch in the sixth and seventh positions between the *CASF* (92) and the *NAAJ* (101).

While the total number of citations for the sample journals provides a measure of the total impact that each journal has on actuarial research, the total number of citations is greatly affected by the number of citable articles published by the sample journals. For example, if Journal A publishes twice as many articles as Journal B, then Journal A should receive twice as many citations, even if the research published in Journal A is not any more influential than that published in Journal B. To control for the difference in the number of articles that the journals publish, Colquitt creates an impact factor that captures the relative research impact of a journal on a per article basis. The higher the impact factor, the more influential a journal's articles are.

When evaluating the research impact of a journal on a per article basis, the *AB* is ranked first among actuarial journals with an impact factor of 2.0175. This essentially means that the *AB* articles published during the sample period were cited an average of 2.0175 times per article by the sample risk, insurance, and actuarial journals analyzed. Following the *AB* is the *PCAS* (1.9825), *IME* (1.6336), the *SAJ* (1.5656), the *BAJ* (1.3892), the *NAAJ* (1.1746), the *CASF* (0.6078), and the *JAP* (0.2766). When looking at an impact factor adjusted to exclude self-citations, there is a considerable difference in the rankings. The *AB* (1.4561) has the highest impact factor, followed by the *SAJ* (1.1475), the *PCAS* (1.1404), the *NAAJ* (0.8016), *IME* (0.7466), the *BAJ* (0.4162), the *CASF* (0.2778), and the *JAP* (0.1170).

Colquitt also determined the top 12 most frequently cited articles in any of the sample actuarial journals (there were actually 17 articles in all with five being tied for the twelfth spot). All actuarial journals except the *CASF*, the *JAP*, and the *NAAJ* are represented on this list. The *AB* and *IME* lead the list with five articles each. Close behind the *AB* and *IME* is the *PCAS* with four of the top actuarial articles and the *BAJ* and *SAJ* have two and one on the list, respectively. All but one of the articles on the list are from the 1980s and 1990s. Finally, two themes

common to several of the 17 most influential articles published in the sample actuarial journals in recent years are pricing and financial distress, which are the subject of over a third of the articles published.

Actuarial Journal Accessibility

Given the wide-ranging extent of the actuarial profession, and the variety of different specialties within the profession, it is not surprising that such an array of actuarial journals has developed to serve the profession. Advances in mathematics, the recent development of technology that allows quantitative methods that were previously impractical, and shifts in the type of risks that the profession is seeking to address, makes the ability to share advances in the field more important than ever. The actuarial journals help advance the development of actuarial science throughout the world by encouraging the dissemination of research and facilitating the exchange of published articles.

Several of these journals provide free access to all published articles online. Articles published in the *Journal of the Institute of Actuaries* or the *Transactions of the Faculty of Actuaries* are available through the association's website, although articles published in the *BAJ* are only available to members. The complete texts of all articles that have been published in *AB*, the *PCAS* or the *CASF* are available at no charge through the CAS website. Abstracts of articles published in the *JAP* are available on their website. Articles in other journals are available to subscribers of online journal services.

Actuary

The word *actuary* derives from the Latin word *actuarius*, who was the business manager of the Senate of Ancient Rome. It was first applied to a mathematician of an insurance company in 1775 in the Equitable Life Insurance Society of London, United Kingdom. By the middle of the nineteenth century, actuaries were active in life insurance, friendly societies, and pension schemes. As time has gone on, actuaries have also grown in importance in relation to general insurance, investment, health care, social security, and also in other financial applications in banking, corporate finance, and financial engineering.

Over the times there have been made several attempts to give a concise definition of the term *actuary*. No such attempted definition has succeeded in becoming universally accepted. As a starting point, reference is made to The International Actuarial Association (IAA)'s description of what actuaries *are*:

Actuaries are multiskilled strategic thinkers, trained in the theory and application of mathematics, statistics, economics, probability and finance

and what they *do*:

Using sophisticated analytical techniques, actuaries confidently make financial sense of the short term as well as the distant future by identifying, projecting and managing a spectrum of contingent and financial risks.

This essay will adopt a descriptive approach to what actuaries are and what they do, specifically by considering the actuarial community from the following angles:

- actuarial science, the foundation upon which actuarial practice rests;
- actuarial practice;
- some characteristics of the actuarial profession.

Actuarial Science

Actuarial science provides a structured and rigid approach to modeling and analyzing uncertain outcomes of events that may impose or imply financial losses or liabilities upon individuals or organizations. Different events with which actuarial science

is concerned – in the following called *actuarial events* – are typically described and classified according to specific actuarial practice fields, which will be discussed later.

A few examples of actuarial events are as follows:

- An individual's remaining lifetime, which is decisive for the outcome of a life insurance undertaking and for a retirement pension obligation.
- The number of fires and their associated losses within a certain period of time and within a certain geographical region, which is decisive for the profit or loss of a fire insurance portfolio.
- Investment return on a portfolio of financial assets that an insurance provider or a pension fund has invested in, which is decisive for the financial performance of the provider in question.

Given that uncertainty is a main characteristic of actuarial events, it follows that probability must be the cornerstone in the structure of actuarial science. Probability in turn rests on pure mathematics.

In order to enable probabilistic modeling of actuarial events to be a realistic and representative description of real-life phenomena, understanding of the “physical nature” of the events under consideration is a basic prerequisite. Pure mathematics and pure probability must therefore be supplemented with and supported by the sciences that deal with such “physical nature” understanding of actuarial events. Examples are death and disability modeling and modeling of financial market behavior.

It follows that actuarial science is not a self-contained scientific field. It builds on and is the synthesis of several other mathematically related scientific fields: pure mathematics, probability, mathematical statistics, computer science, economics, finance, and investments. Where these disciplines come together in a synthesis geared directly toward actuarial applications, terms like actuarial mathematics and insurance mathematics are often adopted.

To many actuaries, both in academia and in the business world, this synthesis of several other disciplines is “the jewel in the crown”, which they find particularly interesting, challenging, and rewarding.

Actuarial Practice

The main practice areas for actuaries can broadly be divided into the following three categories:

- life insurance and pensions (*see* **Life Insurance Markets; Longevity Risk and Life Annuities**)
- general/nonlife insurance (*see* **Nonlife Insurance Markets**)
- financial risk (*see* **Distributions for Loss Modeling**).

There are certain functions in which actuaries have a statutory role. Evaluation of reserves in life and general insurance and in pension funds is an actuarial process, and it is a requirement under the legislation in most countries that this evaluation is undertaken and certified by an appointed actuary. The role of an appointed actuary has long traditions in life insurance and in pension funds (*see* **Longevity Risk and Life Annuities**). A similar requirement has been introduced by an increasing number of countries since the early 1990s.

The involvement of an actuary can be required as a matter of substance (although not by legislation) in other functions. An example is the involvement of actuaries in corporations' accounting for occupational pensions. An estimate of the value of accrued pension rights is a key figure that goes into this accounting, and this requires an actuarial valuation. Although the actuary who has undertaken the valuation does not have a formal role in the general auditing process, auditors would usually require that the valuation be undertaken and reported by a qualified actuary. In this way, involvement by an actuary is almost as it was legislated.

Then there are functions where actuarial qualifications are neither a formal nor a substantial requirement, but where actuarial qualifications are perceived to be a necessity.

Outside of the domain that is restricted to actuaries, they compete with professionals with similar or tangent qualifications. Examples are statisticians, operations researchers, and financial engineers.

Life Insurance and Pensions

Assessing and controlling the risk of life insurance and pension undertakings is the origin of actuarial practice and the actuarial profession. The success in managing the risk in this area comprised the following basics:

- understanding lifetime as a stochastic phenomena, and modeling it within a probabilistic framework;
- understanding, modeling, and evaluating the diversifying effect of aggregating lifetime of several individuals into one portfolio;
- estimating individual death and survival probabilities from historic observations.

This foundation is still the basis for actuarial practice in the life insurance and pensions fields.

A starting point is that the mathematical expectation of the present value of (the stochastic) future payment streams represented by the obligation is an unbiased estimate of the (stochastic) actual value of the obligation. Equipped with an unbiased estimate and with the power of the law of large numbers, the comforting result that actual performance in a large life insurance or pension portfolio can "almost surely" be replaced by the expected performance.

By basing calculations on expected present values, life insurance and pensions actuaries can essentially do away with frequency risk in their portfolios, provided their portfolios are of a reasonable size. Everyday routine calculations of premiums and premium reserves are derived from expected present values (*see* **Premium Calculation and Insurance Pricing**).

Since risk and stochastic is not explicitly present in the formulae that life insurance and pensions actuaries develop and use for premium and premium reserve calculations, their valuation methods are sometimes referred to as deterministic. Using this notion may in fact be misleading, since it disguises the fact that the management process is based on an underlying stochastic and risk-based model.

If there was no risk other than frequency risk in a life insurance and pensions portfolio, the story could have been completed at this point. However, this would be an oversimplification, and for purposes of a real-world description life insurance and pensions actuaries need to take also other risks (*see* **Axiomatic Measures of Risk and Risk-Value Models; Basic Concepts of Insurance**) into consideration. Two prominent such risks are model risk and financial risk.

Model risk represents the problem that a description of the stochastic nature of different individuals' lifetimes may not be representative for the actual nature of today's and tomorrow's actual behavior of that phenomenon. This is indeed a very substantial risk since life insurance and pension undertakings usually involve very long durations (*see* **Estimation of Mortality Rates from Insurance Data**).

The actuarial approach to solving this problem has been to adopt a more pessimistic view of the future than one should realistically expect. Premium and premium reserves are calculated as expected present values of payment streams under the pessimistic outlook. In doing so, frequency risk under the pessimistic outlook is diversified. Corresponding premiums and premium reserves will then be systematically overstated under the realistic outlook.

By operating in two different worlds at the same time, one realistic and one pessimistic, actuaries safeguard against the risk that what one believes to be pessimistic *ex ante* will in fact turn out to be realistic *ex post*. In this way, the actuary's valuation method has been equipped with an implicit safety margin against the possibility of a future less prosperous than one should reasonably expect. This is safeguarding against a systematic risk, whereas requiring large portfolios to achieve diversification is safeguarding against random variations around the systematic trend.

As time evolves the next step is to assess how experience actually has been borne out in comparison with both the pessimistic and the realistic outlook, and to evaluate the economic results that actual experience gives rise to. If actual experience is more favorable than the pessimistic outlook, a systematic surplus will emerge over time. The very purpose of the pessimistic outlook valuation is to generate such a development.

In life insurance it is generally accepted that, when policyholders pay premiums as determined by the pessimistic world outlook, the excess premium relative to the realistic world outlook should be perceived as a deposit to provide for their own security. Accordingly, the surplus emerging from the implicit safety margins should be treated differently from ordinary shareholders' profit. The overriding principle is that when surplus has emerged, and when it is perceived to be safe to release some of it, it should be returned to the policyholders. Designing and controlling the dynamics of emerging surplus and its reversion to the policyholders is a key activity for actuaries in life insurance.

The actuarial community has adopted some technical terms for the key components that go into this process:

- pessimistic outlook: first-order basis
- realistic outlook: second-order basis

- surplus reverted to policyholders: bonus.

By analyzing historic data and projecting future trends, life insurance actuaries constantly maintain both their first-order and their second-order bases. Premium and premium reserve valuation tariffs and systems are built on the first-order basis. Over time emerging surplus is evaluated and analyzed by source, and in due course reverted as policyholders' bonus.

This dynamic and cyclic process arises from the need to protect against systematic risk for the pattern of lifetime, frequency and timing of death occurrences, etc. As mentioned above, another risk factor not dealt with under the stochastic mortality and disability models is financial risk.

The traditional actuarial approach to financial risk has been inspired by the first-order/second-order basis approach. Specifically, any explicit randomness in investment return has been disregarded in actuarial models, by fixing a first-order interest rate that is so low that it will "almost surely" be achieved. This simplified approach has its shortcomings, and we describe a more modernized approach to financial risk under the section titled "Finance".

A life insurance undertaking typically is a contractual agreement of payment of nominally fixed insurance amounts in return for nominally fixed premiums. Funds for occupational pensions, on the other hand, can be considered as prefunding vehicles for long-term pension payments linked to future salary and inflation levels. For employers' financial planning it is important to have an understanding of the impact that future salary levels and inflation have on the extent of the pension obligations, both in expected terms and in terms of the associated risk. This represents an additional dimension that actuaries need to take into consideration in the valuation of pension fund's liabilities. It also means that the first-order/second-order perspective that is crucial for life insurers is of less importance for pension funds, at least from the employer's perspective.

General Insurance

Over the years actuaries have attained a growing importance in the running of the nonlife insurance operations. The basis for the insurance industry is to accept economic risks. An insurance contract may give rise to claims. Both the number of claims

and their sizes are unknown to the company. Thus insurance involves uncertainty and here is where the actuaries have their prerogative; they are experts in insurance mathematics and statistics.

Uncertainty is perhaps even more an issue in nonlife than in the life insurance industry, mainly due to the catastrophic claims such as natural disasters. Even in large portfolios substantial fluctuations may occur.

In some countries it is required by law for the nonlife insurance companies to have an appointed actuary to approve the level of reserves and premiums and report to the supervisory authorities.

The most important working areas for nonlife actuaries in addition to statutory reporting are as follows:

- reserving
- pricing
- reviewing reinsurance program
- profit analyses
- budgeting
- product development
- produce statistics.

Reserving

It takes time from the occurrence of a claim until it is being reported to the company and even more time until the claim is finally settled. For instance, in accident insurance the claim is usually reported rather quickly to the company but it may take a long time until the size of the claim is known since it depends on the medical condition of the insured. The same goes for fire insurance where it normally takes a short time until the claim is reported but it may take a long time to rebuild the house. In liability insurance it may take a very long time from the occurrence of a claim until it is reported. One example is product liability in the pharmaceutical industry where it may take a very long time until the dangerous side effects of a medicine are revealed. The insurance company has to make allowance for future payments on claims already incurred. The actuary has a key role in the calculation of these reserves. The reserves may be split into IBNR reserves (incurred but not reported) and RBNS reserves (reported but not settled) (*see Securitization/Life*). As the names suggest the former is a provision for claims already occurred but have not yet been reported to the company. The latter is a provision for claims already

reported to the company but have not yet been finally settled, that is, future payments will occur. The actuary is responsible for the assessment of the IBNR reserves and several models and methods have been developed. The RBNS reserves are mainly fixed on an individual basis by the claims handler based on the information at hand. The actuary is, however, involved in the assessment of standard reserves, which is used when the claims handler has too scarce information to reach a reliable estimate. In some lines of business where claims are frequent and moderate in size, for instance, windscreen insurance in motor, the actuary may help in estimating a standard reserve that is used for all these claims in order to reduce administration costs. In some cases the RBNS reserves are insufficient and it is necessary to make an additional reserve. This reserve is usually called an *IBNER reserve (incurred but not enough reserved)*. However, some actuaries denote the sum of (pure) IBNR reserve and the insufficient RBNS reserve as the IBNER reserve.

Pricing

Insurance companies sell a product whose exact price is unknown to them. Actuaries can therefore help in estimating the price of the insurance product. The price will depend on several factors; the insurance conditions, the geographical location of the insured object, the age of the policyholder, etc. The actuary will estimate the impact on the price of the product from each of the factors and produce a rating table or structure. The salesmen will use the rating table to produce a price for the insurance product. The actuaries will also assist in reviewing the wording of insurance contracts in order to maintain the risks at an acceptable level. The actuaries may also assist in producing underwriting guidelines. The actuary will also monitor the overall premium level of the company in order to maintain profitability.

Reinsurance (see Reinsurance)

For most insurance companies, it will be necessary to reduce their risk by purchasing reinsurance. In this way a part of the risk is transferred to the reinsurance company. The actuary may help in assessing the necessary level of reinsurance to purchase.

Profit analyses

Analyzing the profitability of an insurance product is a complex matter involving taking into account

the premium income, investment income, payments and reserves of claims, and finally the administration costs. Thus the actuary will be a prime contributor to such analyses.

Budgeting

Actuaries may also help in developing profit and loss accounts and balance sheets for future years.

Product development

New risks or the evolvement of existing risks may require development of new products or alteration of existing products. Actuaries will assist in this work.

Statistics

To perform the above analyses, reliable and consistent data are required. Producing risk statistics is therefore an important responsibility for the actuary.

It is important for the actuary to understand the underlying risk processes and to develop relevant models and methods for the various tasks. In most lines of business the random fluctuation is substantial. This creates several challenges for the actuary. One major challenge is the catastrophic claims. Taking such claims into full consideration would distort any rating table. On the contrary, the insurance company would have to pay the large claims as well and this should be reflected in the premium.

Finance

Financial risk (*see* **Model Risk; Integration of Risk Types**) has grown to become a relatively new area for actuarial practice. Actuaries who practice in this field are called “actuaries of the third kind” within the actuarial community, perhaps also among nonactuaries.

Financial risk has always been present in all insurance and pensions undertakings, and in capital accumulating undertakings as a quite dominant risk factor. As mentioned under the section titled “Life Insurance and Pension”, the “traditional approach” to this risk has been disregarded by assumption, by stipulating future liabilities with a discount rate that was so low that it would “almost surely” be realized over time.

Financial risk is different from ordinary insurance risk in that increasing the size of a portfolio does not in itself provide any diversification effect. For

actuaries it has been a disappointing and maybe also a discouraging fact that the law of large numbers does not come into assistance in this regard.

During the last half-century or so, new perspectives on how explicit probabilistic approaches can be applied to analyze and manage financial risk have developed. The most fundamental and innovative result in this theory of financial risk/mathematical finance is probably that (under certain conditions!) risk associated with contingent financial claims can in fact be completely eliminated by appropriate portfolio management.

This theory is the cornerstone in a new practice field that has developed over the last decades and is called *financial engineering*. Activities in this field include quantitative modeling and analysis, funds management, interest rate performance measurement, asset allocation, and model-based scenario testing. Actuaries may practice financial engineering in their own right, or they may apply financial engineering as an added dimension to traditional insurance-orientated actuarial work.

A field where traditional actuarial methods and methods relating to financial risk are beautifully aligned is asset liability management (ALM). The overriding objective of ALM is to gain insight into how a certain amount of money is best allocated among given financial assets, in order to fulfill specific obligations represented by a future payment stream. The analysis of the obligation’s payment stream rests on traditional actuarial science, the analysis of the asset allocation problem falls under the umbrella of financial risks, and the blending of the two is a challenge that requires insight into both and the ability to understand and model how financial risk and insurance risk interact. Many actuaries have found this to be an interesting and rewarding area, and ALM is today a key component in the risk management of insurance providers, pension funds, and other financial institutions around the world.

A tendency in the design of life insurance products in the recent decades has been unbundling. This development, paralleled by the progress in the financial derivatives theory, has disclosed that many life insurance products have in fact option- or option-like elements built into them. Examples are interest rate guarantees, surrender options, and renewal options. Understanding these options from a financial risk perspective, pricing and managing them is an area of active actuarial research and where actuarial practice

is also making interesting progress. At the time of writing this article, meeting long-term interest rate guarantees is a major challenge with which the life and pensions insurance industry throughout the world is struggling.

A new challenge on the horizon is the requirement for insurers to prepare financial reports on a market-based principle, which the International Accounting Standards Board has had under preparation for some time. In order to build and apply models and valuation tools that are consistent with this principle, actuaries will be required to combine traditional actuarial thinking with ideas and methods from economics and finance.

With the financial services industry becoming increasingly complex, understanding and managing financial risk in general and in combination with insurance risk in particular could be expected to expand the actuarial territory in the future.

Characteristics of Profession

Actuaries are distinguished from other professionals in their qualifications and in the roles they fill in business and society. They also distinguish themselves from other professionals by belonging to an actuarial organization.

The first professional association, The Institute of Actuaries, was established in London in 1848, and by the turn of the nineteenth century, 10 national actuarial associations were in existence. Most developed countries now have an actuarial profession and an association to which they belong.

The role and the activity of the actuarial associations vary substantially from country to country. Activities that an association may or may not be involved in include

- expressing public opinion on behalf of the actuarial profession;
- providing or approving basic and/or continued education;
- setting codes of conduct;
- developing and monitoring standards of practice;
- involvement in or support to actuarial research.

There are also regional groupings of actuarial association, including the grouping of associations from the European Union (EU) European Economic Area (EEA) member countries, the Southeast Asian grouping, and the associations from Canada, Mexico, and United States.

The IAA, founded in 1895, is the worldwide confederation of professional actuarial associations (also with some individual members from countries that do not have a national actuarial association). It is IAA's ambition to represent the actuarial profession globally, and to enhance the recognition of the profession and of actuarial ideas. IAA focuses on professionalism, actuarial practice, education and continued professional development, and the interface with governments and international agencies. Actuarial professions, which are full members of IAA, are required to have in place a code of conduct, a formal disciplinary process and a due process for adopting standards of practice, and to comply with the IAA educational syllabus guidelines.

Hazards Insurance: A Brief History

ARNE EYLAND AND PÅL LILLEVOLD

Adverse Selection

If an insurer sets a premium based on the average probability of a loss in an entire population, those at higher-than-average risk for a certain hazard will benefit most from coverage, and hence will be the most likely to purchase insurance for that hazard. In an extreme case, the poor risks will be the only purchasers of coverage, and the insurer can expect to lose money on each policy sold. This situation, referred to as *adverse selection*, occurs when the insurer cannot distinguish between members of good- and poor-risk categories in setting premiums. This article discusses the implications of adverse selection for insurance.

An Example of Adverse Selection

The assumption underlying adverse selection is that purchasers of insurance have an informational advantage over providers because they know their own true *risk types*. Insurers, on the other hand, must collect information to distinguish between risks.

Example: Private Information about Risk Types Creates Inefficiencies

Suppose some homes have a 10% probability of suffering damage (the “good” risks) and others have a 30% probability (the “poor” risks). If the loss in the event of damage is \$100 for both groups and if there are an equal number of potentially insurable individuals in each risk class, then the expected loss for a random individual in the population is $0.5 \times (0.1 \times \$00) + 0.5 \times (0.3 \times \$100) = \$20$. If the insurer charges an actuarially fair premium across the entire population, then only the poor-risk class would normally purchase coverage, since their expected loss is \$30 ($= 0.3 \times \100), and they would be pleased to pay only \$20 for the insurance. The good risks have an expected loss of \$10 ($= 0.1 \times \100), so they probably would not pay \$20 for coverage. If only the poor risks purchase coverage, the insurer will suffer an expected loss of $-\$10$, $(\$20 - \$30)$, on each policy it sells.

Managing Adverse Selection

There are two main ways for insurers to deal with adverse selection. If the company knows the probabilities associated with good and bad risks, it can raise the premium to at least \$30 so that it will not lose money on any individual. This is likely to produce a partial market failure, as many individuals who might want to purchase coverage will not do so at this high rate. Alternatively, the insurer can design and offer a “separating contract” [1]. More specifically, it can offer two different price-coverage contracts that induce different risk “types” to separate themselves in their insurance-purchasing decisions. For example, contract 1 could offer price = \$30 and coverage = \$100, while contract 2 might offer price = \$10 and coverage = \$40. If the poor risks preferred contract 1 over contract 2, and the good risks preferred contract 2 over contract 1, then the insurer could offer coverage to both groups while still breaking even. A third approach is for the insurer to collect information to reduce uncertainty about true risks, but this may be expensive.

Conclusion

In summary, the problem of adverse selection only emerges if the persons considering the purchase of insurance have more accurate private information on the probability of a loss than do the firms selling coverage. If the policyholders have no better data than the insurers, coverage will be offered at a single premium based on the average risk, and both good and poor risks will want to purchase policies.

HOWARD KUNREUTHER

Air Pollution Risk

Concern about air pollution risk takes two main forms. The first is the greenhouse effect – the collective contribution of a group of gases (known as *greenhouse gases*), which results in global warming and has potentially catastrophic consequences for our climate. The best-known greenhouse gas, and the one on which most emission-reduction attempts are focused, is carbon dioxide (CO_2). However, since this encyclopedia contains a separate entry on *global warming* (see **Global Warming**), we shall not consider it any further here. The second major risk, and the focus of this article, is the effect of air pollution on human health.

As an illustration of one of the major recent studies of this phenomenon, Figure 1 (taken from [1]) shows the results of a time series study based on 88 US cities. For each city, there is a plot of the regression coefficient and 95% confidence interval for the estimated percentage increase in mortality corresponding to a $10\mu\text{g m}^{-3}$ rise in particulate matter of aerodynamic diameter less than $10\mu\text{m}$ (PM_{10}), a size at which particles are capable of penetrating directly into the lungs. Other studies have focused on $\text{PM}_{2.5}$, which has the same definition with a maximum diameter of $2.5\mu\text{m}$.

The cities are grouped into seven regions, and the figure also shows a posterior mean and 95% posterior interval of the pooled effect across each region. Finally, at the right-hand side of the figure the estimated national effect is shown: this shows a posterior mean increased mortality of 0.21% with a posterior standard deviation of 0.06%. Other results from the so-called National Morbidity and Mortality Air Pollution Study (NMMAPS) have included a similar study of ozone [2] and the effect of $\text{PM}_{2.5}$ on hospital admissions [3]. These and other results have been extensively cited in recent years as evidence for tightening the U.S. air pollution standards.

The remainder of this article covers the background and history of this subject, followed by a detailed description of time series studies. Other study designs are also covered, followed by some of the caveats that have been expressed about this whole area of research.

Background and History

The first studies of the impact of air pollution on human health were done in the 1950s, as a result of several dramatic incidents of extremely high air pollution causing widespread death. Possibly the best known of these incidents was the London “smog” of December 5–8, 1952, during which the level of “British smoke” rose to over $3000\mu\text{g m}^{-3}$ and the result was around 4000 excess deaths over what would normally have been expected during this period. Similar incidents in other places led to global concern about the consequences of high air pollution, and motivated the introduction of legislation such as the (British) Clean Air Act of 1956 and the (US) Clean Air Act of 1970, which were the first attempts to deal with the issue by regulation.

Despite the success of these early attempts at eliminating very high pollution events, concern persisted that even at much lower levels pollution was still responsible for adverse health effects, including premature death. Analysis of long-term data records from London ([4, 5], amongst others) prompted researchers to start compiling and analyzing time series from several U.S. cities (e.g. [6–9]). Most of these showed that, after adjusting for effects due to seasonal variation and meteorology, a strong correlation remained between PM and mortality. Other studies showed similar associations with various measures of morbidity, for example, hospital admissions or asthma attacks among children. However, some authors focused on the sensitivity of these results to modeling assumptions and suggested they were not statistically reliable [10, 11].

This background led to a number of large-scale research efforts, the best known of which is NMMAPS. In the next section, we outline the methodology behind these studies.

Time Series Analyses

Although there are many variants on the basic methodology, most of these are close to the following method.

The analyses depend on multiple regressions in which the dependent variable y_t , $t = 1, \dots, n$ is either the death count or some measure of morbidity (e.g., hospital admissions) on day t . Typically the death counts exclude accidental deaths and they may

an explanation were true, there should be observed negative correlations to account for the temporary decrease in the population of susceptible individuals. Studies have repeatedly failed to demonstrate such correlations [12, 13].) Sometimes pollutants other than the main one of interest are included as possible “copollutants”, e.g., in a study of PM_{10} , we may include SO_2 as a copollutant to adjust for the possible confounding of those two effects.

For (b), temperature is almost always included, as well as at least one variable representing humidity, and there may be lagged values as well. The NMMAPS papers have used temperature and dewpoint as the two variables of interest, both of current day and the average of the three previous days to accommodate lagged effects. Other authors have used either specific or relative humidity instead of dewpoint, and some have also included atmospheric pressure.

For (c), it is conventional to assume that one component of the regression function is some nonlinear function of time that has sufficient degrees of freedom to incorporate both seasonal and long-term trend effects. The nonlinear effect may be modeled as a linear sum over K spline basis functions [14]; here K is the number of “knots” and is the most critical parameter. Typically authors use between 4 and 12 knots/year. Similar representations are sometimes used to treat other variables, such as temperature and dewpoint, nonlinearly, though typically with much smaller K (in the range 3–6).

In addition to the above covariates, the NMMAPS analyses have typically included a day-of-week effect and additional nonlinear terms to represent the interaction of long-term trend with age-group.

The alternative “generalized additive model” or (GAM) approach [15] has also been used for nonlinear effects. Some erroneous results were reported owing to inappropriate use of default convergence criteria and standard error formulae [16], though subsequent research resolved these difficulties and strengthened the methodology [17].

Combining Estimates across Cities

Although the initial application of time series regression analysis was to one city at a time, it has been generally recognized that, to obtain definitive results, it is necessary to combine analyses across many

cities. A typical assumption is that the critical parameter of interest (for example, the regression coefficient relating mortality to PM_{10}) is a random effect for each city, say, θ_c in city c , drawn independently from a normal distribution with mean θ^* and variance τ^2 . However, the *estimate* in city c , denoted $\hat{\theta}_c$, is also treated as random with mean θ_c with a presumed known standard error. On the basis of these assumptions, we could, for example, estimate the national parameters θ^* and τ^2 by restricted maximum likelihood, followed by smoothed (or “shrinkage”) estimates of the individual θ_c ’s. Alternatively, researchers have taken a Bayesian approach (see **Bayesian Statistics in Quantitative Risk Assessment**) to the whole analysis, for example using the TLNISE software of Everson and Morris [18]. Some attempts have been made to extend the basic random-effects model to allow for spatially dependent effects [19].

The results of Figure 1 result from application of this methodology to data on 88 US cities from 1987 to 2000. The air pollution variable was daily PM_{10} , lagged 1 day. Other covariates at each city include long-term trend, temperature and dewpoint (current day plus average of the three previous days, using splines to allow for a nonlinear effect), day of week, and an interaction term between the long-term trend and age-group. Most of the attention has been focused on the regional and national “overall” results, where point and interval estimates are given for θ^* .

Alternative Study Designs

Prospective Studies

Apart from time series analysis, there are two other commonly used study designs. *Prospective studies* take a specific cohort of individuals and follow them through a long time period (see **Cohort Studies**). This has the advantage of allowing researchers to measure long-term effects, which is not possible in time series studies. However, unlike time series studies in which regression parameters are computed for each city, and only later combined across cities to achieve greater precision, in prospective studies the regressions themselves rely on between-city comparisons, typically estimating a standardized mortality rate for each city and regressing on some citywide measure of air pollution. This raises issues associated with ecological bias, or in other words, the possibility

that between-city variations may be owing to effects that have nothing to do with air pollution.

Reference [20] presents results from the Harvard Six Cities study, a long-term study of over 8000 individuals in six U.S. cities. Survival rates were conducted using the Cox regression model and showed that, after adjusting for smoking and other known risk factors, there was a statistically significant association between air pollution and mortality. A subsequent paper [21] showed similar results based on a much larger study (the American Cancer Society or (ACS) study), which involved over 500 000 individuals from 154 U.S. cities. Although the study involved many more participants, in other respects it was inferior to the Six Cities study, for example in using participants recruited by volunteers rather than a randomized sample, and in relying essentially on air pollution measures at a single point in time. A third study is the Adventist Health Study of Smog (AHSMOG), which showed similar results for a cohort of over 6000 non-smoking California Seventh-day Adventists [22].

Given the importance of these studies for regulation, the Health Effects Institute commissioned an independent reanalysis of the Six Cities and ACS studies [23]. This study recreated the datasets and largely confirmed the correctness of the original analyses. However, they also conducted many sensitivity analyses, some of which raised doubts about the interpretation of results. We refer to these in more detail in the section titled “Issues and Controversies”.

Case-Crossover Studies

A third paradigm for the design of air pollution–mortality studies is the *case-crossover design*. The idea is to compare the exposure of an individual to a pollutant immediately prior to some catastrophic event (e.g., death and heart attack) with the exposure of the same individual to the same pollutant at other control or “referent” times. Making plausible assumptions about how the risk of the catastrophic event depends both on time and covariates, it is possible to write down likelihood estimating equations (for a regression coefficient between the pollutant and the risk of the catastrophic event) that look very similar to the Poisson-regression equations that arise in time series studies. However, a source of bias is the time interval between the catastrophic event and the selected referent times: if it is too long the analysis may be biased owing to trend, and if it is too

short it could be affected by autocorrelation. References [24, 25] used (respectively) simulation and theoretical arguments to examine the bias issue. The case-crossover methodology was applied [26] to out-of-hospital sudden cardiac arrest in the Seattle region, finding no significant relationship between high air pollution and mortality, which the authors attributed to the lack of prior history of coronary artery disease in the subjects under study, in contrast with other studies that have included patients with such history.

Issues and Controversies

Despite the enormous amount of research that has been done on air pollution and health, the scientific community is by no means unanimous about the interpretation of these studies, especially in the context of regulations about air quality standards. Extended commentaries have been provided [27, 28]; here we summarize a few of the issues that have been raised.

None of the study designs we have discussed are controlled, randomized studies of the sort that are common in, for instance, drug testing. Therefore, they are all vulnerable to possible confounders or “effect modifiers”. Despite serious efforts to include such effects as covariates in the regression analyses, the results typically remain sensitive to exactly which covariates are included or certain *ad hoc* decisions about how to include them (for example, when long-term trends are modeled nonlinearly using splines, how many degrees of freedom to include in the spline representation). See [11, 29] for issues related to model selection or model averaging; the recent paper [30] contains a particularly comprehensive discussion of the degrees of freedom issue.

Most studies have assumed a linear relationship between dose and response (possibly after transformation, e.g., $\log \mu_t$ in the case of Poisson-regression time series analysis). But this is arguably inappropriate for regulatory decisions in which it is critical to assess the likely benefit of a specific reduction in pollution (for example, if the 8-h ozone standard were reduced from 80 to 60 parts per billion). Bell *et al.* [31] presented nonlinear models for ozone; the earlier authors did the same for PM [32–34] with varying conclusions.

The question of whether to focus on fine particles or coarse particles has been the cause of much debate.

Much of the research and regulatory effort over the past decade has been focused on fine particles ($PM_{2.5}$), which penetrate deeper into the lungs and are therefore widely believed to have a more significant health effect. However, to consider one example, Smith *et al.* [34] reached the opposite conclusion while analyzing epidemiological data from Phoenix, Arizona.

The criticisms that have been raised regarding cohort studies are somewhat different, but ultimately the basic issue is whether the associations found in studies are indicative of a true causal effect. Krewski *et al.* [23] introduced a number of “ecological covariates” on a citywide scale to determine whether the intercity PM effects that had been observed in earlier studies could be due to other sources. In the case of the ACS dataset, they examined some 20 possible ecological covariates; all but two were not statistically significant, but one of those that was significant was gaseous sulfur dioxide (SO_2). The picture was further clouded when spatial correlations were introduced into the model; in one analysis, involving both SO_2 and sulfate particles in a model with spatial dependence, the “particles” effect was not statistically significant, though the SO_2 effect still was significant. It has been speculated [35] that these inconsistencies in the results of different cohort studies may be due to an inappropriate assumption of proportional hazards in the Cox regression model.

Summary and Conclusions

The Environmental Protection Agency has recently finalized a new $PM_{2.5}$ standard – controversially from the point of view of some epidemiologists, it did not lower the long-term average level permitted from the standard of $15 \mu g m^{-3}$ that was introduced in 1997. A possible lowering of the ozone standard, from its present value of 80 parts per billion, is still under consideration. Other countries have similar standards in force that in some cases are lower than in the United States. Both advocates and opponents of tightened standards draw heavily on the epidemiological studies that have been discussed in this article, so their interpretation has significant political and societal implications. In the view of this author, new research over the past decade has added enormously to the information available about health effects, but there remain fundamental controversies that may never be fully resolved.

Alternative Risk Transfer

Active management of risk is an important element of any corporate strategy designed to increase enterprise value (the discounted value of future after-tax profits), and traditional loss financing mechanisms such as full insurance/reinsurance contracts (*see* **Reinsurance**), are widely used in support of this goal. These conventional techniques have been supplemented since the mid- to late 1990s by solutions from the alternative risk transfer (ART) market, which we define as the combined risk-management marketplace for innovative loss financing programs. The ART market comprises various products, vehicles, and solutions, including the following:

- Partial insurance and finite risk contracts, which finance, rather than transfer, risk exposures.
- Multirisk contracts, which transfer multiple risks simultaneously.
- Insurance-linked securities, which securitize, and then transfer, insurable risks to capital markets investors.
- Contingent capital, which provides a company with securities or bank financing in the aftermath of an insurable loss event, at a cost determined *ex ante*.
- Insurance derivatives, which allow hedging of insurable risk through a direct transfer to capital markets institutions.
- Captives, which facilitate and economize a company's self-directed risk financing or risk transfer strategies.
- Enterprise risk-management programs, which combine disparate risks, time horizons, and instruments into a single, multiyear risk plan.

The ART marketplace is considered “alternative” because it expands conventional risk-management horizons, allowing companies to consolidate risks, alter cash flows and time horizons, utilize a full range of “hybrid” insurance and banking mechanisms, and attract capital from the insurance sector and global capital markets at the lowest possible cost.

Partial Insurance and Finite Risk Contracts

Full insurance can be considered a maximum risk transfer contract where the ceding company shifts

to an insurer as much exposure as possible at an economically fair premium. Full insurance is characterized by small deductibles, large policy caps, limited coinsurance, and narrow exclusions. Partial insurance contracts, in contrast, involve a far greater amount of retention. By increasing the deductible, lowering the policy cap, and increasing coinsurance and exclusions the ceding company retains more risk and pays the insurer a lower premium (*see* **Premium Calculation and Insurance Pricing**). This is equivalent to partial financing rather than transfer, and a simple cost/benefit exercise will reveal whether the strategy actually serves to increase enterprise value.

Finite risk contracts, such as loss portfolio transfers and adverse development cover, are partial insurance mechanisms that are commonly used to manage the risks associated with loss exposures or the rate of loss accrual. They serve primarily as cash flow timing, rather than loss transfer, mechanisms, offering balance sheet, and cash flow protection rather than capital protection.

Consider the example of a company that wishes to create more stable cash flows while transferring a small amount of property and casualty (P&C) risk exposure. The company enters into a 3-year finite policy where it pays \$2 million of premium/year into an experience account that earns 5% interest (taxable at a marginal corporate rate of 34%). The company favors this arrangement because the \$2 million reflects a certain, predictable cash outflow. In order to establish and maintain the program, the company pays an insurer an annual fee equal to 10% of premium. Any P&C losses that occur over the 3-year period are funded through the experience account and any shortfall is split between the company and insurer on a 90%/10% basis. Table 1 reflects assumed loss experience of \$1, \$2, and \$5 million and the resulting cash flows under the finite contract.

The account ends with a deficit of nearly \$2.4 million at the end of year 3, meaning the company will fund approximately \$2.2 million while the insurer will cover the balance. In fact, the company may arrange to fund the shortfall in additional installments over another 3-year period in order to continue smoothing its cash flows, which is its primary goal in creating the finite program.

Table 1 Finite contract cash flows^(a)

	Year 1	Year 2	Year 3
Previous balance	\$0	\$860 000	\$747 000
Premium deposit	\$2 000 000	\$2 000 000	\$2 000 000
Fee	–\$200 000	–\$200 000	–\$200 000
Beginning balance	\$1 800 000	\$2 660 000	\$2 547 000
Claims (loss experience)	–\$1 000 000	–\$2 000 000	–\$5 000 000
After-tax interest	\$60 000	\$87 000	\$85 000
Ending balance	\$860 000	\$747 000	–\$2 368 000

Multirisk Contracts

A multirisk contract (*see* **Risk Measures and Economic Capital for (Re)insurers**), such as the multiple peril or multiple trigger products, combines several exposures or events into a single risk-management instrument, giving a company an efficient, and often cost-effective, risk solution. Since multirisk contracts are based on multiple risks/events, the effects of correlation, and joint probabilities can lead to a more favorable cost of protection, which can strengthen enterprise value.

Multiple peril products, which include commercial umbrella policies and multiline policies, act as risk consolidation programs, combining designated insurable risks into a single, 3- to 7-year policy with an aggregate premium, deductible, and cap. Since coverage is conveyed through a consolidated document, transaction costs and premiums decline, while the risk of overinsurance is reduced. In addition, a company with a multiple peril policy need not be concerned about the specific source of a loss; as long as a loss-inducing peril is named in the policy, indemnification occurs. The scope of insurable risk coverage has broadened in recent years; while the earliest versions of the contract focused on similar risks, disparate risks are now often included (e.g., workers' compensation, environmental liability, and P&C business interruption).

Multiple trigger products, a second type of multirisk contract, provide a company with loss financing only if two or more risk events occur. For instance, a power company supplying electricity to industrial and retail customers might be severely impacted if its generators suffer from mechanical failure (first trigger event) and the price of electricity rises at the same time (second trigger event); under this scenario the higher the power price during interruption, the greater

the loss. If the company is primarily concerned about the financial impact of the joint event, which may be regarded as catastrophic in nature (i.e., high severity/low probability), it can combine the two in a multiple trigger contract and achieve considerable cost savings (*see* **Dependent Insurance Risks; Risk Measures and Economic Capital for (Re)insurers**). For instance, if each of the two events has a 10% likelihood of occurrence, the joint event has only a 1% probability of occurrence, which leads to a reduction in the cost of protection.

Insurance-Linked Securities

Securitization which is the process of removing assets, liabilities, or cash flows from the corporate balance sheet and conveying them to third parties through tradable securities, has been a feature of the financial markets for several decades. In the 1990s, banks began applying securitization techniques, which they had used to good effect in securitizing mortgages, receivables, and credits to the insurance market, creating notes and bonds based on insurance-related events. Most insurance-linked securities issuance is arranged on behalf of insurers and reinsurers that are seeking to transfer risk exposure or create additional risk capacity within their catastrophic P&C portfolios (e.g., hurricane, windstorm, and earthquake). The fundamental mechanism provides access to the global capital markets, which are significantly larger than the insurance/reinsurance markets. This can provide important cost savings, particularly during hard market cycles in insurance/reinsurance.

Under a typical insurance-linked securitization (Figure 1) a special purpose reinsurer issues securities to investors and writes a matching reinsurance

Figure 1 Insurance securitization [Reproduced from [1] with permission from John Wiley & Sons, Inc., © 2004.]

(or retrocession) contract to the insurer (reinsurer). Proceeds from the issue are invested in government securities by the trustee, and the yield on the government collateral together with the premium on the reinsurance combine to form the interest coupon. Actual payment of interest and/or principal is based on losses arising from a defined trigger event: if losses exceed a predetermined threshold as a result of a named event (e.g., earthquake or hurricane), the special purpose reinsurer withholds interest and/or principal payments from investors; if no event occurs, investors receive full interest and principal cash flows. The insurer or reinsurer thus protects itself from losses created by the defined event. Securities can be issued with an indemnity trigger (where cash flows are suspended if the insurer's actual book of business loses a certain amount), a parametric trigger (where cash flows are suspended if a location/severity damage metric exceeds a particular value), or an index trigger (where cash flows are suspended if a loss index exceeds a particular value).

Contingent Capital

Contingent capital is a contractually agreed financing facility that provides a company with funding in the aftermath of a defined insurable loss event. Since the facility is arranged in advance of any loss leading to financial distress, the company's financing cost does not reflect the risk premium that might otherwise be demanded by capital suppliers after a loss. For

instance, if a company that can normally raise 12-month funds at 50 basis points over government rates suffers a very large loss as a result of an insurable event that impairs its financial condition, it may be forced to pay +250 basis points to raise funds, reducing its enterprise value in the process. The contingent capital facility eliminates this incremental financing burden.

In a generic form of the structure (Figure 2) a company identifies an amount of capital that it wishes to raise if a loss occurs, determines the event that can trigger the loss, and defines the specific form of financing it wishes to raise (e.g., debt securities, bank loan, and equity securities). If the event occurs, the capital provider supplies funds at the *ex ante* price. In return, the company pays the capital provider a periodic (or up front), nonrefundable commitment fee (payable whether or not the financing is raised) as well as an underwriting/financing fee (payable only if financing is raised).

Consider the following example. An insurance company arranges a \$500 million 5-year note issue that will be triggered in the event losses in its P&C portfolio exceed \$500 million over the next 2 years. The arranging bank identifies investors that "prefund" a \$500 million trust in exchange for an all-in yield equal to the commitment fee plus the return on 5-year government bond. The \$500 million in prefunding proceeds are used to purchase the bonds. Assume that 1 year from now the insurer's actual P&C loss experience is greater than expected. The

Figure 2 Contingent financing [Reproduced from [1] with permission from John Wiley & Sons, Inc., © 2004.]

insurance company issues \$500 million of 5-year notes to the trust, the trust liquidates its government bonds and uses the proceeds to acquire the notes; the trust now holds the insurance company's notes, the insurer receives \$500 million of cash to help manage its financial position and end investors continue to receive the enhanced yield on the trust-issued notes.

Insurance Derivatives

Derivatives, which can be broadly defined as financial contracts that derive their value from a market reference, permit users to transfer the economics of specific risk references such as equity indexes and interest rates (*see Stochastic Control for Insurance Companies*). The contracts have been actively used by hedgers and speculators for decades to exchange or assume risks of various financial and commodity indexes and can be structured in exchange-traded (listed and standardized) or over-the-counter (bespoke) form. Derivatives have also been applied selectively to insurance risks since the 1990s. The most common, in what is still a relatively small (though growing) market, include catastrophe swaps and noncatastrophic weather contracts. As with other instruments, the intent is to manage risk exposures as efficiently as possible.

An insurer can manage its risk portfolio using the catastrophe reinsurance swap, a synthetic over-the-counter transaction where it exchanges a commitment fee for a contingent payment from its counterparty based on a catastrophic loss. By doing so, the insurer obtains many of the same benefits provided by reinsurance or securitization (e.g., portfolio diversification, exposure reduction, and increased capacity), but without the structural complexities and costs. For

instance, an insurer might pay a reinsurer a funding rate plus a spread over a multiyear period in exchange for \$100 million of contingent catastrophe exposure capacity. If the catastrophe named under the swap occurs and creates a loss, the counterparty provides the ceding insurer with compensation of up to \$100 million and assumes claim rights through subrogation. An insurer can also alter its portfolio through the pure catastrophe swap, a synthetic transaction that provides for the exchange of uncorrelated catastrophe exposures. For instance, a Japanese insurer with excess Japanese earthquake risk may swap a portion of its risk with a US insurer that has excess exposure to North Atlantic hurricanes. Because the two risks are uncorrelated the insurers receive diversification benefits through the swap.

The temperature derivative, an example of a non-catastrophic weather contract (*see Weather Derivatives*), can be used by a company whose revenues or expenses are exposed to changes in temperature. Consider a local gas distribution company delivering gas during the winter season to a base of residential customers. The company favors very cold winters (i.e., those with a high number of heating degree days (HDDs), or days when the average temperature exceeds 65°F), as demand for gas and gas selling prices will both rise. The reverse scenario presents a risk: warm winters (i.e., those with a small number of HDDs) mean less demand and lower prices and, thus, lower revenue. The company can protect its downside risk by selling an exchange-traded HDD future (or over-the-counter swap) based on a proximate reference city. To do so, it quantifies its exposure, determining that its revenues vary by \$1 million for each 100 change in HDDs. A warm season that generates 4700 HDDs *versus* a seasonal budget

of 5000 HDDs leads to a \$3 million loss in revenues, a cool season with 5200 HDDs leads to a \$2 million increase in revenues, and so forth. Assume the company sells 100 futures contracts on the HDD index at a level of 5000. If the season becomes very cold HDDs might rise to 5300, meaning the company loses \$3 million on its futures position; however, it earns an incremental \$3 million in revenues as a result of stronger demand for fuel and higher fuel prices. If the winter is warm, HDDs might only amount to 4700, meaning a \$3 million revenue loss. This, however, will be offset by a \$3 million futures hedge gain.

Captives

A captive is a closely held insurer/reinsurer that a company can establish to self-manage retention/transfer activities. The sponsoring company, as owner, provides up-front capital, receiving periodic interest and/or dividends in return. The captive then insures the owner (or third-party users) by accepting a transfer of risk in exchange for premium. Because insurance premiums normally cover the present value of expected losses, along with insurance acquisition costs, overhead expenses, and profit loading, the non-claims portion of the premium can be as high as 30–40% of the total. A company with highly predictable risks can create a captive in order to save on this nonclaims portion.

The captive, which can be created as a single owner/user structure (e.g., the pure captive) or a multiple owner/multiple user structure (e.g., group captive, agency captive, protected cell company), has proven popular because it provides: appropriate and flexible risk cover, particularly for exposures that might otherwise be hard to insure; lower costs, primarily by avoiding agent and broker commissions and insurance overhead/profit loadings; possible tax

advantages related to investment income, premiums and/or incurred losses; incentives to implement loss control measures; decreased earnings volatility as a result of increased cost predictability; and, incremental profit potential if third-party business is written.

Assume, for instance, that a company faces a predictable level of expected losses in its workers' compensation program and is comfortable retaining a certain amount of risk. Historically, the company has paid \$2 million per year in premiums for a standard insurance policy that transfers its workers' compensation exposure, but has estimated that it can save \$250 000 per year by retaining the risk and reinsuring through a captive. It can establish a pure captive as a licensed reinsurer for a one-time fee of \$200 000 and annual captive management fees of \$50 000. Because the captive is established as a reinsurer, the company must use a fronting insurer, which will require the payment of \$75 000 of annual fronting fees.

The captive is not expected to write third-party business, so the company will obtain no premium tax deductibility benefits. Furthermore, the company does not intend to alter its investment policy on retained funds and is expected to face a 5% cost of capital and a 34% tax rate during the 3-year planning horizon. Given these assumptions, the net present value of the decision on whether to establish and use a captive can be determined through the cash flows shown in Table 2.

The annual cash flows, discounted at a 5% cost of capital, yield a net present value of:

$$\begin{aligned} \$175\,166 = & -\$49\,500 + (\$82\,500/1.05^1) \\ & + (\$82\,500/10.05^2) + (\$82\,500/1.05^3) \end{aligned} \quad (1)$$

Since the figure is positive, the company can increase its enterprise value by retaining its workers'

Table 2 Captive cash flows^(a)

	Start	Year 1	Year 2	Year 3

compensation exposures and insuring them *via* the captive.

Enterprise Risk Management Programs

Enterprise risk management (*see* **Enterprise Risk Management (ERM)**) – a risk-management process that combines disparate financial and operating risks and time horizons into a single, multiyear program of action – can provide a company with an efficient and cost-effective risk solution that may be superior to transactional or “incremental” approaches. A successful program relies on proper identification of all of a company’s risk exposures, and how they interact with one another. Consider a company facing a

series of insurance and financial exposures (Figure 3). Each individual exposure is considered and managed separately, and the end result is a series of individual insurance policies, financial derivatives, and other loss financing techniques that are designed to provide protection. This, however, may be an inefficient way of managing corporate resources, leading to excess costs, overinsurance/overhedging, and capital mismanagement—all of which can reduce enterprise value. Uniting the individual vertical covers under a comprehensive enterprise risk-management program (Figure 4) eliminates coverage gaps, lowers costs, and improves capital and administrative efficiencies.

The platform does not require that all exposures be channeled through a “master” insurance policy.

Figure 3 Individual risk exposures [Reproduced from [1] with permission from John Wiley & Sons, Inc., © 2004.]

Figure 4 Consolidated risk exposures [Reproduced from [1] with permission from John Wiley & Sons, Inc., © 2004.]

For instance, the risk retained under a program can be channeled through a group captive or funded *via* liquid resources, catastrophe coverage can be based on a dual trigger contract and allow for the issuance of incremental equity, returns on an investment portfolio might be floored through the use of equity options, and so on. In fact, such flexibility is a key characteristic and advantage of the enterprise risk-management process.

Arsenic

Arsenic is a naturally occurring element, found throughout the environment in many different forms [1]. Inorganic arsenic compounds, mainly arsenate and arsenite, are commonly detected in soil and some groundwaters. Organic arsenic compounds (i.e., containing carbon) are also found in the environment. The most abundant organic arsenic compound is arsenobetaine, which is commonly detected in seafood and considered relatively nontoxic. Arsenic compounds have also been used as medicines, pesticides, wood preservatives, and animal feed additives. This chapter focuses on the toxicity and risk assessment of inorganic arsenic.

For most chemicals, scientists primarily rely on studies of laboratory animals to evaluate chemical toxicity (*see Cancer Risk Evaluation from Animal Studies*). Arsenic is unusual in that many human populations throughout the world have been or continue to be exposed to high levels of arsenic. Workers in certain fields, such as smelting and certain types of chemical manufacturing, have been exposed to elevated levels of arsenic in air, particularly under historical workplace conditions. Naturally occurring arsenic contamination in groundwater continues to be a concern in certain areas of the world, including parts of Taiwan, India, Mongolia, and Bangladesh. As a result, arsenic has been widely studied in humans and an extensive database of human studies is available. Scientists have not identified a representative animal model for arsenic carcinogenicity in a standard two-year bioassay [2].

Sources and Pathways of Arsenic Exposure

Inorganic arsenic occurs naturally in groundwater, with widely varying concentrations (*see Water Pollution Risk*). Although the median arsenic groundwater concentration is $\leq 1 \mu\text{g l}^{-1}$ in the US., mean well-water concentrations in certain US counties range as high as $190 \mu\text{g l}^{-1}$ [3–5]. Around the world (Taiwan, Bangladesh, China, India, Nepal, and Chile), groundwater concentrations of inorganic arsenic can average several hundred micrograms per liter [6–12]. Such levels result in significant human exposures *via* drinking water, and studies of these populations provide important information about the adverse health effects from chronic arsenic ingestion.

Inorganic arsenic is also naturally present in soil; the natural content of arsenic in soils globally ranges from 0.01 to over 600 mg kg^{-1} , with an average of about $2\text{--}20 \text{ mg kg}^{-1}$ [13]. Soils near smelting sites, or in areas where arsenical pesticides have been used, can contain elevated levels of arsenic. Human exposure to arsenic in soil can occur through incidental ingestion (e.g., while eating or during normal hand-to-mouth contact, particularly for children less than 6 years because of their increased hand-to-mouth contact), absorption from soil through the skin, and inhalation of wind-blown soil particles. As arsenic is not readily absorbed through the skin from soil [14], and the amount of exposure to naturally occurring concentrations of arsenic in soil by inhalation is quite small [15], the ingestion pathway is typically the dominant pathway of exposure for arsenic in soil (*see Soil Contamination Risk*). The bioavailability of arsenic in soil, or the amount of arsenic absorbed into the body from the gut after ingestion, ranges from about 3 to 50%, depending on soil type and test method [16–19], whereas the bioavailability of arsenic in drinking water is close to 100% [1].

Arsenic can enter the air *via* multiple sources. In addition to resuspension of arsenic in soil as airborne dust, arsenic can be also emitted through volcanic eruptions, or released into the air through smelting, municipal waste incineration, or certain other activities [1]. Airborne arsenic is generally not the most significant pathway of arsenic exposure, except in certain occupational settings.

For the general population, food is typically the largest source of arsenic exposure, with dietary exposure accounting for about 70% of the daily intake of inorganic arsenic [20]. The average daily intake of inorganic arsenic in food is about $3 \mu\text{g day}^{-1}$, with a range of about $1\text{--}20 \mu\text{g day}^{-1}$, primarily from grains, fruits, rice, and vegetables [21, 22]. Total arsenic ingestion, including organic arsenobetaines in seafood, is higher, averaging about $2\text{--}92 \mu\text{g day}^{-1}$ [23].

Human Health Effects of Inorganic Arsenic

Acute Health Effects

Arsenic has been used as a poison throughout history; very large oral doses of arsenic can be fatal. Nonetheless, present-day reports of arsenic toxicity

from acute exposure (i.e., high-dose, short-term) are rare [1, 24]. A few reported cases have involved short-term exposure to very high levels of arsenic in well water ($1200\text{--}10\,000\ \mu\text{g l}^{-1}$) [24–26]. Most other information regarding acute arsenic toxicity in humans derives from its medicinal use or from incidents in which individuals were poisoned with arsenic. Acute high doses can lead to effects such as encephalopathy, nausea, anorexia, vomiting, abdominal pain, cardiovascular effects, hepatotoxicity, hematologic abnormalities, vascular lesions, peripheral neuropathy, and death [1]. For example, in a case of contaminated soy-sauce in Japan, doses of about $0.05\ \text{mg kg}^{-1}\ \text{day}^{-1}$ for 2–3 weeks resulted in facial edema and mild gastrointestinal effects [27]. More severe effects, such as damage to the peripheral nervous system, occur only when acute doses are about $2\ \text{mg kg}^{-1}\ \text{day}^{-1}$ or higher (e.g., [26, 28, 29]).

Chronic Health Effects – Noncancer

Chronic exposures to high doses of arsenic are associated with various noncancer health effects in humans, the most sensitive of which are skin and possibly vascular effects [30–32]. There is no convincing association between arsenic exposure in humans and reproductive/developmental effects [30, 33, 34]. Overall, it is not until chronic arsenic doses exceed about $0.01\ \text{mg kg}^{-1}\ \text{day}^{-1}$ that there is an established association between arsenic exposure and noncancer health effects in humans [30].

Skin effects are generally recognized to be the most sensitive and characteristic noncancer effects resulting from long-term exposure to arsenic [1, 30–32, 35, 36]. Arsenic-induced pigmentation changes are often described as a “raindrop” pattern, and arsenic-induced hyperkeratosis is more frequently observed on the palms and soles [37]. A key arsenic epidemiologic study, initially published in 1968 by Tseng *et al.*, investigated over 40 000 Taiwanese people exposed to high levels of arsenic in drinking water [38, 39]. Hyperpigmentation and hyperkeratosis were increased in all exposed groups; the lowest dose at which effects were observed was $170\ \mu\text{g l}^{-1}$. In subsequent studies around the world, similar effect levels for arsenic-induced skin changes have been reported [40–44]. Skin effects have also been observed in workers exposed to arsenic in air ranging as high as $1\text{--}100\ \text{mg m}^{-3}$ [1, 45–48].

Consumption of high levels of arsenic in drinking water in non-US populations has also been associated with vascular effects, including peripheral vascular disease, high blood pressure, cardiovascular and cerebrovascular disease, circulatory problems, ischemic heart disease, and Raynaud’s disease [49–58]. In contrast, there is no convincing evidence for cardiovascular effects in US studies [5, 30, 59]. “Blackfoot disease”, a vascular disease characterized by loss of circulation in the hands and feet, is endemic in certain areas of Taiwan with $170\text{--}800\ \mu\text{g l}^{-1}$ arsenic in drinking water, but has not been reported outside of Taiwan [1, 30, 39]. Furthermore, dietary deficits and other drinking water contaminants may play a causative role in Blackfoot disease in Taiwan [60]. The evidence for an association between inhaled arsenic and cardiovascular effects is more limited; despite an increase in cardiovascular disease, some of the studies failed to show a clear dose–response relationship (e.g., [61, 62]).

Long-term exposure to high doses of arsenic can lead to peripheral neuropathy, but reports of neurological effects at lower arsenic doses are inconsistent [1, 63–65]. For example, chronic exposures to arsenic in drinking water in China (mean $158.3\ \mu\text{g l}^{-1}$) were not associated with changes in nerve conduction velocity [66]. In contrast, in a recent Bangladesh study (mean arsenic, $115\ \mu\text{g l}^{-1}$), the authors reported a significant association between toe vibration threshold (a “subclinical” indicator of sensory neuropathy) and some, but not all, measures of exposure.

A limited number of publications have reported an association between elevated arsenic exposure (milligrams of arsenic ingested per day) and diabetes mellitus [30, 67–71]. Because diabetes mellitus occurs only at high arsenic exposures, and often in conjunction with skin effects, it is not considered a sensitive arsenic-induced health endpoint [35]. Gastrointestinal symptoms have also been reported with chronic exposures to arsenic, but generally not until exposures of $0.04\ \text{mg kg}^{-1}\ \text{day}^{-1}$ or more, and usually in conjunction with skin effects [1, 30, 40, 41, 43, 72].

Chronic Health Effects – Cancer

On the basis of studies of human populations outside the United States, arsenic has been classified as a “human carcinogen” by the United States Environmental Protection Agency (US EPA) [73] and

as “carcinogenic to humans” by the International Agency for Research on Cancer (IARC), part of the World Health Organization (WHO) [74]. Exposure to high levels of arsenic in drinking water, usually greater than $150\text{ }\mu\text{g l}^{-1}$, is associated with cancer of the lung, bladder, and skin, in multiple studies conducted in countries such as Taiwan [39, 75–78], Chile [11], Bangladesh [6], and Inner Mongolia [79]. A number of other cancers, such as kidney and liver cancer, have been associated with exposure to high levels of arsenic in drinking water, but the associations are not as strong and have not been consistently observed [35]. Reports linking arsenic exposure to other cancers (e.g., prostate, colon, stomach, nasal, laryngeal, and leukemia) are isolated, inconsistent, and lack sufficient statistical substantiation [5, 35, 58, 80, 81].

The most comprehensive study on skin cancer was performed by Tseng *et al.* [39]; they compared skin cancer incidence in an arsenic-exposed population of over 40 000 people and identified a dose-dependent relationship between arsenic and skin cancer. In the 1980s, a series of epidemiologic studies were published reporting the relationship between arsenic exposure and other cancer sites in the same Southwestern Taiwanese population studied by Tseng *et al.* [38, 39]. Chen *et al.* found increased cancer deaths from bladder, kidney, skin, lung, liver, and colon cancers in individuals exposed to artesian well water and made some general statements about the relationship between arsenic exposure and increased cancer incidence [82]. In a follow-up study of over 32 000 people from 42 different villages with arsenic concentrations ranging from 10 to $935\text{ }\mu\text{g l}^{-1}$, Wu *et al.* found that mortality increased with increasing arsenic concentrations in water for cancers of the bladder, kidney, skin, lung, liver, prostate, and leukemia [58]. US EPA has relied solely on these Taiwanese studies to develop the cancer toxicity factors used in risk assessments, and, thus, arsenic regulatory standards and criteria are based on the Taiwanese data. However, while the Taiwanese studies are useful because of their large size and quantitative information regarding high doses of arsenic and cancer, they offer limited information about the effects of arsenic at low doses.

With respect to bladder cancer, results from international epidemiologic studies have shown effects only at relatively high ($>150\text{ }\mu\text{g l}^{-1}$) arsenic exposure levels, if at all. Bates *et al.* found no association between arsenic ingestion and bladder cancer

in Argentina, even at concentrations $>200\text{ }\mu\text{g l}^{-1}$, contradicting a finding of increased bladder cancer at lower, but less well defined, arsenic exposures in an earlier Argentinean study [83, 84]. In a Taiwanese study, Chiou *et al.* found no increase in bladder cancer incidence in Taiwan [78], even at arsenic levels of $710\text{ }\mu\text{g l}^{-1}$ in drinking water [30]. Guo *et al.* found a statistically significant increase in bladder cancer only at arsenic concentrations of $640\text{ }\mu\text{g l}^{-1}$ or more in drinking water [76]. Lamm *et al.* reanalyzed data from Taiwan and concluded that arsenic-induced bladder cancer occurs only at levels $>400\text{ }\mu\text{g l}^{-1}$, and that certain artesian wells in Taiwan may have contained contaminants (e.g., humic acids, fluorescent substances, and fungi) that increase the potency of arsenic [85]. Lamm *et al.* subsequently reanalyzed the extensive Taiwanese dataset, and demonstrated that geographically related risk factors (by township) for bladder and lung cancer may have distorted previous analyses of these data [86]. Separating out these factors by excluding townships where arsenic well water was not the most important determinant of cancer, Lamm revealed that the dose–response for arsenic-related bladder and lung cancer had an apparent threshold, increasing only at concentrations above $150\text{ }\mu\text{g l}^{-1}$ in drinking water.

Lung cancer has been associated with both arsenic ingestion (*via* drinking water) and inhalation. Guo reported elevated lung cancer mortality in Taiwan at concentrations $>640\text{ }\mu\text{g l}^{-1}$ in drinking water [77], although in a different Taiwanese population, Chiou *et al.* did not find an increase in lung cancer with exposures to arsenic levels of $710\text{ }\mu\text{g l}^{-1}$ and higher [30, 78]. Workers with high-dose, long-term occupational exposure to airborne arsenic have also shown an increase in lung cancer [1, 87–89].

Well-designed US epidemiologic studies show no evidence of increased cancer risk at lower arsenic doses. In a large study in Utah [5], US EPA found no convincing evidence of carcinogenic or noncancer effects at average arsenic concentrations in drinking water up to almost $200\text{ }\mu\text{g l}^{-1}$. In a *case–control* study (*see Case–Control Studies*) using estimates of arsenic exposure based on individual intakes, Steinmaus *et al.* found no clear association between arsenic and bladder cancer even in individuals exposed to arsenic in excess of $80\text{ }\mu\text{g day}^{-1}$ for 20 years [4].

Discussion

Overall, consistent noncancer and cancer health effects have been observed only in populations outside the United States with relatively high concentrations of arsenic in drinking water, often in populations suffering from nutritional deficiencies that may increase susceptibility to arsenic [72, 90, 91]. Extrapolation of health risks from arsenic drinking water studies conducted outside the United States may lead to an overestimate of risks for populations where arsenic exposures are significantly lower and nutritional status is better.

Interestingly, there are no reliable studies demonstrating that ingestion of arsenic-contaminated soil or dust has led to toxicity. Several studies have shown that chronic exposure to arsenic in soil at concentrations $>100 \text{ mg kg}^{-1}$ is not associated with an increase in body burden or adverse effects [92–96].

Arsenic Measurement in Humans

Urine arsenic measurements are considered a useful biomarker for recent arsenic exposures. Most inorganic arsenic is excreted from the body in urine within 1–2 days, and typical urine arsenic levels in the United States are about $50 \mu\text{g l}^{-1}$ or less [30, 97]. Since levels of arsenic in urine can vary on the basis of dietary habits (seafood consumption can raise levels up to $2000 \mu\text{g l}^{-1}$), it can be important for laboratories to distinguish arsenobetaine (the relatively nontoxic form of arsenic in seafood) from inorganic arsenic and its metabolites.

Arsenic in hair and fingernail can be a qualitative way to assess long-term exposure to arsenic, confirming past exposures up to 6–12 months. Normal arsenic levels in hair and nails are 1 mg kg^{-1} or less [1]. Measurements of nail and hair arsenic may be misleading due to the presence of arsenic adsorbed to the external surfaces of hair and fingernail clippings [1, 97]. Arsenic clears the bloodstream within a few hours of exposure [98], and is therefore a poor means to quantify arsenic exposure.

Arsenic Risk Assessment

Arsenic Toxicity Criteria

Assessing arsenic health risks involves consideration of the magnitude, duration, and route of arsenic

exposure, together with toxicity information from epidemiologic studies. US EPA uses noncancer and cancer toxicity information to develop chemical-specific toxicity factors; these values are published on the Integrated Risk Information System (IRIS). The IRIS database serves as an important resource because it allows scientists to standardize the risk assessment process, using a common set of toxicity criteria.

Noncancer. The US EPA oral reference dose (RfD) for arsenic, a chronic dose that is believed to be without significant risk of causing adverse noncancer effects in even susceptible humans, is $0.0003 \text{ mg kg}^{-1} \text{ day}^{-1}$, based on skin and vascular lesions in the Taiwanese study by Tseng *et al.* [39]. The Agency for Toxic Substances and Disease Registry (ATSDR) independently develops chemical-specific toxicity criteria based on noncancer health effects. The ATSDR minimal risk level (MRL) for arsenic, an “estimate of daily human exposure to a substance that is likely without an appreciable risk of adverse effects (noncarcinogenic) over a specified duration of exposure”, is also $0.0003 \text{ mg kg}^{-1} \text{ day}^{-1}$ for chronic oral exposures, based on the Tseng *et al.* study [1, 39]. ATSDR has also developed a provisional MRL of $0.005 \text{ mg kg}^{-1} \text{ day}^{-1}$ for acute-duration (≤ 14 days) oral exposures [1]. Neither EPA nor ATSDR has developed a toxicity factor for noncancer effects of inhaled arsenic.

Cancer – Oral Arsenic Exposures. For compounds that are considered known or likely carcinogens, the US EPA develops cancer slope factors (CSFs) using mathematical models to extrapolate risks observed at high doses (either in humans or animals) to lower doses reflective of more typical human exposure levels. Use of a CSF to quantify cancer risks often involves the default assumption that the dose–response relationship is linear at low doses. That is, even a very small dose of arsenic confers some excess cancer risk, and as the dose increases linearly, the risk increases linearly. For many compounds, including arsenic, it is likely that this assumption is not correct; the dose–response relationship is likely to be sublinear or have a threshold [99]. From a toxicological perspective, this means that low doses of arsenic would be relatively less effective than higher doses, and may, in fact, be associated with zero risk.

The oral cancer potency of inorganic arsenic as well as the assumption of linearity has been a source of substantial scientific debate, giving rise to several different evaluations of the carcinogenic potency of arsenic (Table 1). Analyses by US government agencies have suggested CSFs for arsenic ranging from 0.4 to 23 kg day mg⁻¹, an almost 60-fold range. Differences are mainly dependent on the type of cancer used in the evaluation, assumptions used to relate the high-dose Taiwanese data to low-dose arsenic exposure in the US, and choice of control populations. The US EPA CSF for arsenic of 1.5 kg day mg⁻¹ that is currently published on IRIS [73] is based on skin cancer in the Tseng Taiwan study [39]. Although there are several more recent CSF evaluations for arsenic, EPA has not yet updated the arsenic CSF value published on IRIS, and thus, 1.5 kg day mg⁻¹ is used most commonly in arsenic risk assessments.

Although the various evaluations of the arsenic CSF use different assumptions to arrive at different quantitative estimates of the potency of arsenic, all the analyses contain certain conservative elements and are thus likely to overestimate arsenic cancer risk for United States and other Western populations with generally low to modest levels of arsenic exposure. There are considerable scientific concerns about the exposure estimates in the Taiwanese study. Individual exposures were not characterized, and

exposures were based on average arsenic concentrations of groundwater in wells in each village [105]. What is particularly relevant is the recent evidence of a confounding factor in well water from certain townships that was associated with cancer [86]. Genetic factors, dietary patterns, and other lifestyle factors may alter arsenic metabolism and detoxification [106–108]. Nutritional deficiencies contribute to arsenic susceptibility [72, 90, 91]. Therefore, the use of a CSF derived based on relatively high levels of arsenic in water in a population with nutritional deficiencies (e.g., Taiwan) may overestimate cancer risks for populations where arsenic exposures are significantly lower and nutritional status is better.

Finally, there is convincing human and mechanistic data supporting a nonlinear dose–response relationship for arsenic. As discussed above, US studies do not indicate an increased cancer risk, even with levels as high as 200 µg l⁻¹ in drinking water, and in other parts of the world, arsenic does not cause bladder, lung, or skin cancer until levels in drinking water are greater than 150 µg l⁻¹ (e.g. [85, 86]). The indication from human studies for a nonlinear or threshold dose–response for arsenic carcinogenicity is further supported by a mechanistic understanding of how arsenic interacts with DNA to produce carcinogenic changes. Specifically, arsenic does not interact directly with DNA to produce point

Table 1 Summary of US cancer slope factors for arsenic

Slope factor (mg/kg-day) ⁻¹	Source	Agency	Comments
1.5	Integrated Risk Information System (IRIS)	US EPA [73]	Currently listed in IRIS; based on skin cancer incidence in Taiwan
0.4–3.67	Final rule for arsenic maximum contaminant level (MCL) for arsenic in drinking water	US EPA [100]	Based on bladder and lung as opposed to skin cancer; also based on Taiwanese water intake and arsenic in food
As high as 23	National Research Council (NRC) arsenic in drinking water report	National Academy of Sciences (NAS), review panel for US EPA [35]	Based on lung and bladder cancer risk in Taiwan, using more conservative modeling assumptions
3.67	Draft Chromated Copper Arsenate (CCA) reregistration, CCA risk assessment, and organic arsenic herbicide reregistration	US EPA [101–103]	Based on upper range established in MCL rule
0.41–23	Petition to ban CCA wood	Consumer Product Safety Commission (CPSC)	Based on EPA and NRC assessments
5.7	Proposed IRIS revision	US EPA [104]	Based on bladder and lung cancer; incorporates many of NRC's recommendations

mutations, but instead may modify DNA function through one or more indirect mechanisms, including chromosome alterations, changes in methylation status of DNA, and alterations in gene transcription [99, 109]. This indicates that arsenic carcinogenicity likely has a sublinear dose–response. Thus, assuming a linear dose–response relationship, as the US EPA and National Academy of Sciences (NAS) have done in their assessments, likely overestimates arsenic risk at low levels of exposure.

Cancer – Inhalation Arsenic Exposures. The US EPA inhalation unit risk for arsenic is $4.3 \times 10^{-3} \text{ m}^3 \mu\text{g}^{-1}$, based on linear extrapolation of lung cancer risks from several studies of smelter workers with occupational exposures to airborne arsenic [45, 47, 73, 110–112].

Regulatory Standards and Criteria for Arsenic in Environmental Media

Regulatory standards and criteria for environmental media are derived using toxicity criteria (RfDs and CSFs), human exposure assumptions, and other information. In January 2001, the US EPA lowered the maximum contaminant level (MCL) for arsenic in drinking water from 50 to $10 \mu\text{g l}^{-1}$ [100], based on a reevaluation of the carcinogenic potency of arsenic with a focus on bladder and lung cancer (as opposed to skin cancer). WHO has also set a guideline value of $10 \mu\text{g l}^{-1}$ for arsenic in drinking water [113]. The US EPA soil screening level (SSL) for arsenic in residential settings is 0.4 mg kg^{-1} [15]. As naturally occurring levels of arsenic are often elevated above standard regulatory risk thresholds, it is important for risk managers to put arsenic exposures in perspective, and consider background when setting clean-up levels.

As Low as Reasonably Practicable/As Low as Reasonably Achievable

The *ALARP principle* refers to the notion that risks should be “as low as reasonably practicable”. ALARA, “as low as reasonably achievable”, is generally taken to mean the same, but is used more frequently in the context of radiation protection (*see Risk from Ionizing Radiation*). Certain pieces of legislation, such as the UK Health and Safety at Work Act refer to risks being reduced “so far as is reasonably practicable” (SFAIRP).

The ALARP principle is embedded in UK law, and is applied mainly in the United Kingdom, but has influenced risk acceptance criteria and risk regulation throughout the world. Other important principles include the precautionary principle used in various contexts, and the emerging concept of risk-informed regulation used by the US Nuclear Regulatory Commission.

Much of the legal framework surrounding the ALARP principle is based on the Court of Appeal judgment in the case of *Edwards v the National Coal Board* from 1948:

... in every case, it is the risk that has to be weighed against the measures necessary to eliminate the risk. The greater the risk, no doubt, the less will be the weight to be given to the factor of cost.

and

Reasonably practicable’ is a narrower term than ‘physically possible’ and seems to me to imply that a computation must be made by the owner in which the quantum of risk is placed on one scale and the sacrifice involved in the measures necessary for averting the risk (whether in money, time or trouble) is placed in the other, and that, if it be shown that there is a gross disproportion between them—the risk being insignificant in relation to the sacrifice—the defendants discharge the onus on them.

This brings out the essential elements of ALARP. On the one hand there is a risk, and against that there is a sacrifice required to avert that risk. Only when there is a great disproportion of sacrifice against risk, the duty holder (normally the management of a company carried out activities bearing a degree of risk) does not have to take any steps to reduce that risk.

Modeling an ALARP problem involves, however, making decisions about the bounds of the model: the population at risk, the items to be costed, etc. Studies usually consider hypothetical individuals and different kinds of populations, to ensure that there is no particular subpopulation at more risk than others. Costing is no less difficult, but guidance exists from regulators about what can and cannot be taken into account.

The government regulator (in the United Kingdom, normally the Health and Safety Executive, HSE) is responsible for testing that risk is ALARP, but final responsibility for a particular installation lies with the duty holder, and whether the law has been broken is ultimately a matter for courts rather than the regulator to decide.

While the ALARP principle has been adopted into law, there is little case law to provide guidance and therefore the regulatory authorities have put a great deal of effort into explaining how they interpret the elements of ALARP, that is, how risk is measured, how the sacrifice is to be measured, and what is meant by gross disproportion. These are only the views of the regulator, largely untested in court.

The ALARP principle is applied in the United Kingdom in many different areas. The original applications are in factories, mines, etc., but modern applications are also in transportation (trains, vehicles, tunnels, and airplanes), environment (flood, fire, etc.), medicine, and even the military. The principle has been incorporated into national and international standards, so that it is being applied even in areas where national law does not explicitly use it.

Measuring Risk

In order to balance the changes in risk with the costs of achieving those changes, we should be able to measure risks and costs, and then make them comparable. A later section will discuss the use of cost–benefit analysis, but for now we concentrate on measuring risks.

An extended discussion on risk measurement is given in [1]. However, for the purposes of this paper we can restrict the discussion broadly to simple individual risk measures and societal risk measures.

Individual risk is commonly used to refer to the probability that a specific individual will die as a consequence of the activity under discussion, at some

point in a given 1-year period. Many assumptions have to be made in order to model this risk, one of the most important being the exposure time, the proximity to the risk, and the physical condition of the person involved. For example, calculations for members of the public might conservatively assume that the individual was always exposed, while calculations for workers might assume that exposure only takes place during working hours.

While *individual risk* refers to the risk for a specific individual, *societal risk* refers to the frequency with which events occur leading to multiple fatalities. A common way to illustrate this is with an FN (Frequency-Number) curve, which shows the frequency of events (per year) involving the death of at least N individuals, ($N = 1, 2, 3, \dots$).

Various other risk measures are used in different sectors. For example, in the nuclear industry it is also common to discuss the risk of exposure to a given level of radiation. As these may be difficult to assess, core damage frequencies are also used as risk measures.

Often risk measures are applied to different populations. While it is common to distinguish between fatality risks for the public and for the workers, the UK Railway Safety and Standards Board goes further, by distinguishing workers, passengers, and third-party members of the public. It further models minor injuries, major injuries, and fatalities giving nine categories in total. However, for the purpose of making ALARP judgments, these injury categories are considered as “equivalent fatalities” by using weighting factors for each category.

Finally, in some industries it is appropriate to use risk measures that are normalized by exposure time. An example of this is the fatal accident rate (FAR) used in the maritime and offshore industries. This measures accidents per hour (or million hours) of working hours.

Tolerability of Risk

As a result of the Sizewell B Enquiry in the United Kingdom, it was recommended that HSE develops guidance on “tolerable” levels of risk to members of the public and to workers from nuclear power plants. The use of the word “tolerable” was quite new, as the common usage then was to talk about “acceptability” of risk. The subtle distinction is used to indicate that

Figure 1 Tolerability of risk triangle [From [2], 1988. Health and Safety Executive. © Crown copyright material is reproduced with the permission of the Controller of HMSO and Que Printer for Scotland.]

we never accept a level of risk, but tolerate it in return for other benefits that we obtain through the activity that generates the risk.

The tolerability of risk (TOR) guidance document [2] produced by HSE in 1988 (revised in 1992) introduced the TOR triangle shown in Figure 1.

Activities that generate a high level of risk are considered intolerable under all circumstances. At the lower end, there is a level below which risk is considered to be negligible, and therefore so low that it is not worth the cost of actively managing it. There is a region between these two limits, called the *ALARP* or the *tolerability region*, in which it is necessary to make a trade-off between risk and the cost of further risk reduction.

In keeping with the Court of Appeal judgment in the *Edwards v The National Coal Board* case, the issue of whether or not a particular risk is tolerable in the ALARP region depends on whether or not the cost of reducing it *further* would be disproportionate to the risk. Furthermore, the degree of disproportionality depends on how big the risk is.

The TOR guidance suggested an upper limit of individual risk for workers as 1 in 1000 per year, and 1 in 10 000 for the public for nonnuclear industrial risks, and 1 in 100 000 for the public for nuclear risks.

In safety assessment principles (SAPs), the upper and lower risk limits are called *basic safety limit* (BSL) and *basic safety objective* (BSO). A number of different measurement scales are used, so that BSLs and BSOs are defined for diverse quantities such as annual radiation exposure of a member of the public,

worker radiation dose, plant damage frequency, and critical event frequency. Hence, in principle at least, there are a number of different measurement scales on which the ALARP principle would be applied.

In order to determine the level of risk, a probabilistic safety analysis (PSA) is used (in nonnuclear industries the term *quantitative risk analysis* (QRA) is used more frequently). It should be noted however that, in general, good engineering practice is more of a driver of actual design and operating safety decisions than PSA.

The HSE's *Reducing Risks, Protecting People* [3] describes the ALARP region as follows:

The zone between the unacceptable and broadly acceptable regions is the tolerable region.

Risks in that region are typical of the risks from activities that people are prepared to tolerate in order to secure benefits, in the expectation that:

- the nature and level of the risks are properly assessed and the results used properly to determine control measures. The assessment of the risks needs to be based on the best available scientific evidence and, where evidence is lacking, on the best available scientific advice;
- the residual risks are not unduly high and kept as low as reasonably practicable (the ALARP principle. . .); and
- the risks are periodically reviewed to ensure that they still meet the ALARP criteria, for example, by ascertaining whether further or new control measures need to be introduced to take into account changes over time, such as new knowledge about the risk or the availability of new techniques for reducing or eliminating risks.

While the ALARP region is generally taken to apply to individual risk measures, something very similar is used for societal risk measures. Indeed, several governments have included FN criteria in legislation or risk regulation, among others being The Netherlands, which had upper and lower limits similar to the BSO and BSL used by the SAPs for individual risk [4].

Measuring “The Sacrifice” Required to Reduce Risk

As we have seen, the original court judgment introducing the notion that we now call ALARP discussed the need to balance risk with the sacrifice required to reduce that risk.

Current practice is to measure “sacrifice” in monetary terms, using cost–benefit analysis. There are three main difficulties in this regard:

1. defining the scope of the analysis, in terms of time, geography, scale, etc;
2. quantifying monetary values for items that are not normally traded commodities, such as human lives, plant and animal species, and so on;
3. dealing costs and benefits accrued at different points of time.

Analysis scope is very difficult to determine because of the wide range of possible knock-on effects that might result from a change to a system. In some cases the scope is simply defined by a regulation or law, as in the Dutch definition of societal risk that includes only short-term fatalities. In other cases, the scope is not always clear and might affect the outcome of the analysis – for example, if one considers the idea of introducing seat belts in trains then this restricts capacity and therefore increases road-use and associated environmental costs.

The quantification of monetary values for items that are not traded is the subject of a large literature within the area of cost–benefit analysis (*see Cost-Effectiveness Analysis*). There has been much criticism of this, in particular; see [5]. In the context of this short article, we shall concentrate on the concept of the value of a statistical life, often also called the *value of preventing a fatality* (VPF).

While the layperson's view of VPF is often that it represents an actual valuation of a human life, with all the unpleasant moral associations that it brings, this is not the view taken by most professionals. Indeed, the UK HSE [3] states as follows:

VPF is often misunderstood to mean that a value is being placed on a life. This is not the case. It is simply another way of saying what people are prepared to pay to secure a certain averaged risk reduction. A VPF of £1 000 000 corresponds to a reduction in risk of one in a hundred thousand being worth about £10 to an average individual. VPF therefore, is not to be confused with the value society, or the courts, might put on the life of a real person or the compensation appropriate to its loss.

This interpretation is of interest because it relates the definition of VPF to its use in risk decision making. In practice, one is not trying to decide whether or not a particular person (a “statistical person” does

not, of course, exist) should live or die, but whether a particular person (in fact the particular group of people exposed to risk) should have a change to that risk. For this society has to commit resources, and has to determine an appropriate amount.

The HSE view [3] is that the VPF should be the same for each type of risk, except for cancer, where the VPF is doubled. The VPF used in the United Kingdom is of the order of £ 1 million, and was originally developed by the UK Department of Transport. While consistency of the VPF is a reasonable administrative objective, it seems reasonable to suggest that in determining priorities for risk reduction (for example, through budget setting), some types of risk are prioritized over others – for example, multiple fatality accidents as opposed to suicides.

The VPF is typically determined through stated preference techniques, particularly contingent valuation and choice modeling. In the former, respondents have to state how much they would be willing to pay for a reduction in risk and this is converted to a VPF. Choice modeling is a more general class of techniques in which a VPF can be inferred from rankings of different choices offered to the participant. For a longer discussion of issues related to stated preference modeling, see [6, 7].

Within cost–benefit analysis, the standard way of comparing items from different time periods is to use discounting. Clearly, the way costs and benefits are discounted over time plays an important role in determining the relative overall balance. Reference [3] suggests using a standard real interest rate of 6% for costs and benefits, but then states the following:

“The value that individuals place on safety benefits tends to increase as living standards improve, so the future values applied to such benefits should be uprated to allow for the impact on well-being of expected growth in average real income. On the basis of past trends and Treasury guidance, HSE regards an uprating factor of 4% a year as appropriate on the benefits side of the comparison.”

Discounting has been criticized for use in studies with very long timescales; see, for example [8].

Criticisms of ALARP

ALARP is widely used in the United Kingdom, but has not been adopted consistently elsewhere, though many countries have regulatory frameworks that, to

some extent, resemble ALARP; see, for example, the discussion of Norwegian FAR regulations in [9].

There are a number of problems with the cost–benefit analysis element to ALARP. French *et al.* [10], following Adams [5], explore the problems with the difference between willingness to pay (WTP) and willingness to accept (WTA) evaluations. Essentially, the difference in the way a contingent valuation question is posed (WTP or WTA) substantially affects the values obtained. French *et al.* [10] argue that the usual starting point is that people have a right not to be exposed to risks, and that therefore a WTA formulation is appropriate, while in practice WTP is used. They also make a comparison to multiattribute decision making, and discuss problems with the interpretation of “gross disproportionality”.

Kletz [11] points out that in practice the amount of money used to save a human life varies by orders of magnitude between the health service, road safety, chemical industry, and the nuclear industry. He also points to problems arising from the bounding of ALARP analysis. For example, he says that the rebuilt Flixborough site (after the 1974 explosion) was designed to use a safer chemical ingredient than before the disaster. However, this had to be manufactured elsewhere using a process that was at least as risky as the process that had taken place at Flixborough previously. The risk had been exported, out of Flixborough and out of the ALARP calculation.

Examples of ALARP

An example of ALARP case is described in [12]. The authors describe work carried out during the design of the BP Andrew oil platform whose objective was to assess and reduce the risk of impairing the temporary refuge owing to gas explosion and/or ingress of gas or smoke. These had been assessed as the main drivers of risk to the temporary refuge—a unit built away from the main accommodation module on the platform to act as an emergency area. The case illustrated the way in which design changes can be found, which both reduce cost and reduce risk. This case was different from many other applications that take place during the upgrading of existing installations, but shows how beneficial it is to include ALARP considerations in the design phase. In this particular case, the team was able to find new design solutions that lowered risk and saved money.

Ingress of gas and smoke was modeled using computational fluid dynamics models and wind tunnel tests. This enabled the designers to find a position for the air intake pipe for the temporary refuge that was least susceptible to gas and smoke intake, and to estimate the probability of unacceptable ingress in the worst-case scenario. Gas explosions were modeled using a Flame Acceleration Simulator – a computer code that had been previously developed by an industry consortium to model the effect of equipment layout and wall arrangements on combustion and turbulence. Again, a worst-case scenario was computed. Hence, the derived quantitative risks are against those that are considered worst-case scenarios rather than averaged over all scenarios. This is common practice and gives some risk margin, which has enabled some industries to argue later that even when equipment is degraded in later life they are still within ALARP bounds.

Conclusions

The ALARP principle has been the guiding principle for UK risk regulation for several decades and has provided a good basis for consistency of decision making across different sectors. Consistency is achieved on the basis of a number of slightly arbitrary choices in risk limits, VPF, and so on. In practice, this consistency is sometimes undermined by higher level choices, such as budget setting, on the part of decision makers. Finally, the application of ALARP requires the setting of boundaries around the problem area, and the outcome of ALARP decisions may depend on these boundaries. Having said this, ALARP has proved itself in practice to be a reasonably robust approach capable of application across a wide range of sectors.

Asbestos

“Asbestos”, derived from the Greek word meaning “unquenchable” or “indestructible” is a general term applied to a family of fibrous hydrated magnesium silicates [1]. Use of asbestos dating back to ancient times has been documented by the Finnish (2500 B.C. in pottery) and the Romans (400–500 B.C. in lamp wicks and cremation cloths). It was not until the late 1800s, however, that asbestos was mined commercially. Since this time, owing to its strength, flexibility, and heat resistance, asbestos has been incorporated into over 3000 commonly used products, such as oven mitts, driveway sealer, and automotive brakes and clutches [2–7].

Mineralogic Features of Asbestos

Asbestos is composed of two distinct mineralogic groups, the amphiboles and the serpentines. The amphibole group consists of five minerals, including, crocidolite, amosite, anthophyllite, tremolite, and actinolite. Of these, only crocidolite and amosite, also known as blue and brown asbestos, respectively, were mined and used commercially. The remaining amphiboles are primarily considered contaminants of other minerals, such as chrysotile, vermiculite, and talc [8, 9]. Amphibole fibers are rhombic in shape, and consist of chain structures, with nine structural sites that accommodate cations. The principal cations are magnesium, iron, calcium, and sodium, and their ratios can be used to distinguish between the mineral species [10]. Amphibole crystals are characterized as double chain inosilicates, in which the two side-by-side chains share one oxygen molecule per pair of silica tetrahedral. Members of this family have very similar crystal structures, and therefore cannot be distinguished by electron diffraction [9].

The most well-known amphibole deposits, predominantly of crocidolite, are located in South Africa and Australia. The use of amphiboles was banned in most countries between the early 1970s and the mid-1980s, prior to which amphibole asbestos was widely used in asbestos-cement and various insulation products. In fact, from the 1940s to the 1960s, the US Navy often required the use of amosite asbestos pipe and boiler insulation on naval ships. Amosite was particularly suitable for naval use, owing to its resistance

to degradation by salt water. In general, during the years of war, amphiboles were the fiber type of choice for the products used by the navy due to their thermal conductivity, light weight, high tensile strength, and refractoriness [11].

The serpentine group, which is structurally and biologically different from that of the amphiboles, consists solely of chrysotile, or “white asbestos”. Unlike the amphiboles, chrysotile exists as a phyllosilicate, which wraps around itself in a spiral, forming a hollow tubular macrostructure [10]. Chrysotile typically exists in fiber bundles, and consists of varying quantities of individual fibrils. As the name “serpentine” suggests, this class of minerals are known for their snake-like, curly or wavy appearance. This form of asbestos has accounted for roughly 96% of the asbestos production and consumption worldwide from 1900 to 2003, and of the estimated 2.15 million tons of asbestos produced in 2003, it is likely that all but a few thousand tons were chrysotile [12, 13]. Mining of this mineral has mainly occurred in Canada, Russia, Zimbabwe, and the United States, with Canada dominating the industry for most of the twentieth century. Current worldwide chrysotile uses include gaskets, roofing and friction products, corrugated and flat sheets, fittings, and pipes [12].

Pathways of Exposure

By far, inhalation of asbestos fibers is the most important human health hazard. However, humans can be exposed to asbestos fibers *via* ingestion since they have also been detected in potable water supplies [14–19], predominantly at concentrations below 1 million fibers/l [20]. Several sources of the asbestos have been proposed, including the erosion of natural deposits or waste piles, rain water that has run off of asbestos-cement shingles, and leaching from asbestos-cement pipe [16, 21]. Despite the presence of fibers in drinking water, the weight of the scientific evidence indicates that asbestos ingestion does not cause any significant noncancer or carcinogenic health effects [21, 22].

Toxicology of Inhaled Asbestos

There are several factors that are believed to determine the toxicity of inhaled asbestos: fiber dimensions, durability, and chemistry/surface activity.

Fiber Dimensions

The aerodynamic diameter is defined as the diameter of a spherical particle with unit density and the same settling velocity as the actual particle. The aerodynamic diameter of a particle or fiber helps to characterize and define respirability and location of pulmonary deposition. It is believed that particles with aerodynamic diameters between 5 and 30 μm deposit in the nasopharyngeal region, while smaller particles ($\sim 1 \mu\text{m}$) can penetrate more deeply in to the alveolar region of the lungs. In contrast to short, thick fibers, long, thin fibers have small aerodynamic diameters, which allow them to move in parallel with the air stream and deposit deeper into the respiratory tract. Asbestos fibers that are deposited and retained in the alveolar region are most likely to induce a biologically relevant response.

Durability

The durability of an asbestos fiber will influence the rate of fiber clearance. Fibers are generally removed from the lungs *via* the following physiological processes: (a) mucociliary transport (stops at terminal bronchioles), (b) alveolar macrophage translocation, (c) uptake by epithelial cells lining the airways, and (d) lymphatic clearance [23]. In general, clearance from the upper respiratory tract occurs at a faster rate than clearance in the deep lung. For asbestos fibers that reach the alveolar region, the main determinant of the speed of clearance is the rate of phagocytosis. Fiber length is thought to be particularly influential in the pathogenesis of asbestos-related disease, as macrophage-mediated clearance is less effective for long fibers. Further, it has been suggested that fibers greater than the diameter of alveolar macrophages (10–15 μm in rodents, 14–21 μm in humans) are unlikely to be completely phagocytosed [24]. It is believed that this ineffective phagocytosis results in the release of reactive oxygen species and other inflammatory agents. These processes may be one of the causes for the carcinogenic response observed in some animal and human studies.

Numerous studies have supported the assertion that long fibers, regardless of fiber type are more potent than short fibers [25–29]. Recently, the US Environmental Protection Agency (EPA) convened a workshop to discuss a proposed protocol to assess asbestos-related risk [30]. The peer consultation panel concluded that there was considerably greater risk for

developing cancer with asbestos fibers longer than 10 μm and for fibers less than 5 μm the risk was very low and may even be zero [31]. The Agency for Toxic Substances and Disease Registry (ATSDR) also recently sponsored an expert panel to study the influence of fiber length on asbestos health effects [32]. The expert panel also agreed that fibers less than 5 μm pose a negligible risk of cancer [33].

In addition, it has been shown that chrysotile fibers, unlike the amphiboles, undergo longitudinal (splitting) and transverse breaking [23, 34–39]. The effects of the splitting or breaking of chrysotile fibers is unclear. Although some argue that this process renders the chrysotile fibers more apt to macrophage ingestion, others indicate that this may aid in the translocation to the pleural or peritoneal cavities, and the bronchial-associated lymphoid tissue [21, 23].

Chemistry/Surface Activity

Asbestos fibers that are not effectively cleared by physicochemical processes may be removed by other processes, such as dissolution. The physicochemical properties of the different fiber types determine the rate at which they undergo dissolution. Typically, experimentally derived dissolution rates for amphiboles are between 10^{-12} and $10^{-10} \text{ mol m}^{-2} \text{ s}^{-1}$. In contrast, at 37 °C and under conditions similar to the physiological environment in the lung, a dissolution rate of $5.9 \times 10^{-10} \text{ mol m}^{-2} \text{ s}^{-1}$ has been observed for chrysotile asbestos [40]. The practical implications of such dissolution are that an amphibole fiber will not dissolve in a human lung over the course of a lifetime, while a chrysotile fiber, even as thick as 1 μm , would be expected to dissolve in the human lung in less than 1 year [24].

The differing rates of dissolution are the result of the orientation of the magnesium molecules within the fiber types. While magnesium is present to varying degrees in all types of asbestos (e.g., 33% by weight in chrysotile and 6–25% by weight in amphiboles), in chrysotile, the magnesium is located on the outside of the macrostructure, rendering it accessible to lung fluids. On the contrary, the magnesium molecules in the amphiboles are locked within the I-beam type structure, which consists of corner-linked $(\text{SiO}_4)_4$ tetrahedra linked together in a double tetrahedral chain that sandwiches a layer with the $\text{Ca}_2 \text{Mg}_5$ [23]. Numerous studies have demonstrated that, upon exposure to mildly acidic solutions, or even water, the

magnesia completely dissociates from the chrysotile fiber [41–44]. Upon dissociation of the magnesia, the dimensional stability of the chrysotile fibril is lost [45].

The variability in iron composition has also been hypothesized to account for the observed difference in the cancer potency of the fiber types. The amphiboles, such as amosite and crocidolite, are composed of between 25 and 36% iron by weight [46]. This is in contrast to 1–5% iron by weight in chrysotile [47]. In general, it is supposed that fibers with more iron associated with them are better free radical generators, and thus are more biologically active [48, 49]. The reactive oxygen species are believed to be the result of a Fenton-type (Haber–Weiss) redox cycle, which yields hydroxyl radicals. Although the exact mechanism of fibrosis and tumorigenesis has not been elucidated, it has been proposed that the iron content of fibers has a positive correlation with the activator protein-1 (AP-1) induction [50]. In the presence of iron, AP-1, a redox sensitive transcription factor, induces uncontrolled cell proliferation.

Studies of Health Effects

During the first 30 years of the twentieth century, there were only a few case reports that suggested that exposure to asbestos might be associated with adverse health effects. However, these early case reports provided little, if any, information regarding the specific activities that resulted in exposure, the concentration of airborne particles, or details about the disease in these workers [51]. In 1930, the first epidemiology study confirmed an increased incidence of asbestosis in employees working in dusty factory settings [52]. In the subsequent two decades, with few exceptions, the focus of the more than 30 occupational health studies conducted was on workers performing activities in the dustiest of manufacturing environments [11, 53–83].

The first study conducted on end users of asbestos-containing products was not published until 1946, and reported three cases of asbestosis in 1074 pipe coverers involved in the following operations: (a) laying out and cutting of insulating felt, (b) band sawing insulation blocks and boards, (c) manufacturing of boots and jackets to cover valves and joints, (d) mixing asbestos-cement, (e) molding of block insulation, (f) grinding of scrap material, and (g) application of insulation [11]. Owing to the existing US

Naval specifications, amosite was the major ingredient in insulation material, and comprised up to 94% of the asbestos used in pipe covering. Consequently, owing to the low incidence of asbestosis observed, and the fact that all cases had been employed in shipyards for 20 or more years, the authors reported “it may be concluded that such pipe covering is not a dangerous occupation” [11, p. 16]. In 1949, Dr. Canepa conducted a study on 52 “insulation installers” at the Port of Genoa, and reported 5 cases of “clear and obvious” asbestosis and 10 cases of early asbestosis. This was the first study on asbestos-related health effects focused on end users that suggested an increased risk of asbestosis [70].

In 1951, Gloyne examined 1247 lung sections for the presence of pulmonary diseases attributable to the inhalation of dust, and reported lung cancer in 19.6 and 9.7% of men and women with asbestosis, respectively [84]. This raised the question of the possible link between occupational exposures to asbestos and lung cancer. Soon after, [74] published the first epidemiological study providing solid evidence that occupation and smoking were factors in the development of lung cancer [74]. The authors examined incidence of lung cancer in regard to occupation, and reported that lung cancer patients were 10 times more likely to have worked for at least 5 years in occupations involving the use asbestos than the controls. However, the authors concluded that “the group of steam fitters, boilermakers, and asbestos workers lies on the borderline of statistical significance when the effect of cigarette smoking is controlled” [74]. Thus, at this point, it was unclear whether asbestos exposure alone could cause lung cancer.

In the early 1960s, significant progress was made in regard to health outcomes associated with asbestos exposures. Two pivotal studies were published that highlighted the potential for asbestos-related disease among individuals with relatively low exposures [85, 86]. Wagner *et al.* reported 33 cases of mesothelioma identified among South Africans occupationally exposed to asbestos, as well as those residing in proximity to a crocidolite mine. Mesothelioma was also observed in South Africans with no known occupational exposure to asbestos [86]. Soon after, Dr. Irving Selikoff reported an increased incidence of lung and pleural cancer following a cohort mortality study of 632 insulation workers [87, 88]. This was

the first epidemiology study of persons using a “finished product”, which showed a significant association between asbestos exposure and lung cancer and mesothelioma. Because asbestos was a component of many commercial products, such as automotive friction products (i.e., brakes and clutches), cement pipe, and even oven mitts, questions were soon raised regarding the health hazards of asbestos exposures from end products.

Following the shift in attention from dusty factory workers to end users, numerous occupational cohorts (see **Occupational Cohort Studies**) (e.g., asbestos sprayers, cigarette filter workers, construction workers, shipyard workers, electrochemical plant workers, garage mechanics, locomotive drivers, railroad maintenance workers, and rock salt workers) were the subjects of epidemiology studies [89–97]. As the cumulative number of publications on asbestos rose from about 150 in 1940 to over 10 000 in 2000, increased attention was paid to quantifying historical exposure levels. In addition, the specific characteristics of asbestos fibers in asbestos-exposed

workers were examined in several studies [98, 99]. The results of these studies revealed that many of the workers exposed to serpentine fibers had a significant number of amphibole fibers retained in the lungs, while the chrysotile fibers were cleared from the lungs [51]. In addition, chrysotile miners were found to have developed fewer lung cancers and mesotheliomas when compared to miners exposed to other types of asbestos [100]. Therefore, it was postulated that amphiboles were a more potent asbestos type than chrysotile [101, 102].

A number of researchers have quantified the differences in risk of asbestos-related disease between comparable levels of exposure to airborne chrysotile and amphiboles. For example, Hodgson and Darn-ton [103] concluded that “the exposure specific risk of mesothelioma from the three principal commercial asbestos types is broadly in the ratio 1 : 100 : 500 for chrysotile, amosite and crocidolite, respectively”. This magnitude is similar to that agreed upon by a recently convened panel of experts who issued a report on asbestos-related risk for the EPA. This

Table 1 US occupational asbestos guidelines and regulations

Decade	Year	Agency	Duration	Occupational guideline or standard for asbestos ^(a)
1940s	1946	ACGIH	MAC ^(b) /TLV ^(c) 8-h TWA	5 mppcf
1970s	1971	OSHA	PEL ^(d) 8-h TWA	12 fibers/cc
			PEL: 8-h TWA	5 fibers/cc
			STEL ^(e) 15 min	10 fibers/cc
	1974	ACGIH	TLV: 8-h TWA ^(f)	5 fibers/cc
	1976	OSHA	PEL: 8-h TWA	2 fibers/cc
1980s	1980	ACGIH	STEL: 15 min	10 fibers/cc
			TLV: 8-h TWA	Amosite 0.5 fibers/cc
				Chrysotile 2 fibers/cc
				Crocidolite 0.2 fibers/cc
				Tremolite 0.5 fibers/cc
	1986	OSHA	PEL: 8-h TWA	Other forms 2 fibers/cc
				0.2 fibers/cc
				Short-term exposure limit removed
	1988	OSHA	PEL: 8-h TWA	0.2 fibers/cc
				STEL: 30 min
1990s	1994	OSHA	PEL: 8-h TWA	1.0 fibers/cc
			STEL: 30 min	0.1 fibers/cc
	1998	ACGIH	TLV: 8-h TWA	1.0 fibers/cc
				0.1 fibers/cc (all fiber types)

^(a) Beginning in 1971, regulations were specific to fibers >5 µm in length with an aspect ratio of 3 : 1

^(b) MAC: Maximum Allowable Concentration

^(c) TLV: Threshold Limit Value

^(d) PEL: Permissible Exposure Limit

^(e) STEL: Short Term Exposure Limit

^(f) TWA: Time Weighted Average

report states, “The panelists unanimously agreed that the available epidemiology studies provide compelling evidence that the carcinogenic potency of amphibole fibers is two orders of magnitude greater than that for chrysotile fibers” [104]. Likewise, it has been noted that the risk differential between chrysotile and the two amphibole fibers for lung cancer is between 1 : 10 and 1 : 50 [103].

Regulations

The first guidance level for asbestos in workroom air was proposed by Dreessen *et al.* [62] following a study of asbestos workers in manufacturing settings, in which asbestosis was not observed in individuals with exposures below 5 million particles per cubic foot (mppcf) [62]. In 1946, the American Conference of Governmental Industrial Hygienists (ACGIH) adopted this recommendation as the

Threshold Limit Value (TLV) for occupational exposure to asbestos [105]. In the early 1960s, as the result of the Walsh–Healy Act and the Longshoreman’s Act, 5 mppcf became an enforceable regulatory limit for specific industries. Later that decade the ACGIH issued a Notice of Intended Change, lowering the asbestos guideline from 5 mppcf to 12 fibers/ml as an 8-h time weighted average (TWA) [106]. With the conception of the Occupational Safety and Health Administration (OSHA), the first legally enforceable health standard governing exposure to asbestos in all industries was issued on May 29, 1971. A depiction of the occupational exposure limits set forth by OSHA and the ACGIH is presented in Table 1 [107–115]. Current regulations and guidelines governing exposure to asbestos in the United States and in several other countries are presented in Table 2. For policy rather than scientific reasons, most government agencies have chosen to treat all asbestos

Table 2 Current international asbestos regulations

Country	Agency	Long term occupational exposure limit ^(a) (fibers/cc)	Fiber type
Australia	National Occupational Health and Safety Commission	0.1	All types
Canada (Quebec)	National Public Health Institute of Quebec	1	Actinolite Anthophyllite Chrysotile Tremolite
		0.2	Amosite Crocidolite
Denmark	Danish Working Environment Authority	0.1	All types
France	Ministry of the Employment, Social Cohesion and Lodging	0.1	All types
Germany	German Committee on Hazardous Substances	0.15	All types
Hungary	Ministry of Social Affairs and Health	0.1	All types
Japan	Japan Society for Occupational Health	0.15	Chrysotile
		0.03	All other types
South Africa	Department of Labour/Department of Minerals and Energy	0.2	All forms
Spain	National Institute for Occupational Safety and Health	0.1	All types
Switzerland	Swiss Commission of Occupational Exposure Limit Values	0.01	All types
United Kingdom	Health and Safety Commission	0.01	All types
United States	Occupational Safety and Health Administration	0.01	All types
European Union	European Commission/Scientific Committee for Occupational Exposure Limits to Chemical Agents	0.1	All types

^(a) All long term exposure limits are based on an 8-h TWA, excluding France (1-h reference period) and the United Kingdom (4-h reference period)

fiber types equally, despite evidence of large differences in the potential toxicity between amphibole and chrysotile asbestos.

Assessment of Risk Association with Beryllium Exposure

Beryllium is the lightest of all solid, chemically stable compounds. It is the metal with an atomic number of 4 and a molecular weight of 9.04. The two commercially important ore forms are bertrandite extracted as beryllium hydroxide and beryl extracted as beryllium oxide. In addition to beryllium mined in the United States, three to four times as much is imported, mainly from Brazil. There are two gem forms of beryl: emerald and aquamarine.

Beryllium has a high strength to weight ratio, but the cost of the metal limits its use to the computer, airline, and space industries. In alloy forms, it is widely used in home, commercial, and industrial tools primarily as a hardening agent, and in ceramics. Beryllium exposures are mainly limited to industrial settings of mining, processing, and machining. As exposure to tiny amounts ($1\text{--}2\text{ }\mu\text{g m}^{-3}$) can cause significant health effects, emissions from these industries are carefully scrutinized to protect the surrounding communities.

Hazard Identification

A number of more comprehensive reviews on beryllium toxicity are available [1–9].

Human Toxicity

As with many metals mined as ores, beryllium toxicity was first documented in workers in mining, processing, and machining facilities. Beryllium fluoride was first reported to produce serious health effects in 1933 based on reported cases of bronchitis, broncholitis, and confluent lung densities in beryllium ore extraction workers in Europe [10]. Other reports from Europe and Asia [11] also noted serious health effects in extraction workers, due to beryllium compounds. The first report of health effects due to a beryllium compound in the United States was a 1943 report of three cases of chemical pneumonitis in workers from an extraction plant in Ohio [12]. As the compound was beryllium fluoride, the disease was thought to be due to fluoride rather than

beryllium. As more health concerns were reported from the beryllium industry, the effects seen with soluble forms were significantly different from the effects with insoluble forms. This led to a clinical picture that was very confusing and it did not seem plausible that all of the effects were due to beryllium [13]. The first clear description of a clinical beryllium disease was reported in 1946. Hardy and Tabershaw [14] reported on the case histories of 3 men and 14 women who had been employed for only 17 months in the beryllium industry. The syndrome was described as a delayed chemical pneumonitis accompanied with granulomas in the lung, lymph nodes, and liver. As more cases were reported, it became clear that beryllium was the cause of specific health effects as reported at the Sixth Saranac Symposium in 1947 [15, 16].

In following the cohort in the Hardy and Tabershaw [14] report, six of the women died of what became known as *chronic beryllium disease* (CBD) or *berylliosis*. Autopsies revealed pulmonary granulomas, lung fibrosis, and enlarged heart [14, 17, 18]. CBD is an interstitial lung disease characterized by interstitial cellular infiltration, fulminating edema, and fibrosis, with or without granulomas and does not always develop during exposure, but may suddenly appear 10–15 years after termination of beryllium exposure [3]. Unless treated, the latent form of the disease is usually fatal [19]. Beryllium workers often report symptoms of shortness of breath, fatigue, and weight loss and it should be noted that CBD is a systemic disease causing anemia, anorexia, and granulomas in bone, liver, kidney, and spleen, as well as in the lung [20].

Subsequent study of beryllium workers identified a distinct acute form of beryllium disease [12, 21] as well as a chronic form of the disease [14, 22]. The acute form is seen in some workers regularly exposed to more than $100\text{ }\mu\text{g}$ of Be/m^3 of soluble beryllium compounds and in almost all workers exposed to $1000\text{ }\mu\text{g}$ of Be/m^3 , even for a short time [23]. The disease is characterized by acute pneumonitis and cases involving massive pulmonary edema are often fatal. In workers who survive the pulmonary edema, the disease usually resolves within 1 year after removal from exposure and does not progress to CBD [24]. A total of 10 fatalities among 93 cases of acute beryllium disease were noted in workers from two beryllium processing plants in the United States [25]. These workers had

begun working in the plants prior to 1949 and were exposed to massive levels of beryllium. No new cases of acute beryllium disease have been reported since 1950 except for cases involving an industrial accident [2]. Some of the patients who recovered from the acute disease eventually developed lung cancer [26].

The findings of Van Ordstrand *et al.* [12, 23] and Hardy and Tabershaw [14], along with the conclusions of the Saranac Symposium [15, 16] prompted the Atomic Energy Commission in 1949 to implement a hygienic standard of $2\text{ }\mu\text{g}$ of Be/m^3 as a quarterly daily weighted average (DWA) with a ceiling of $25\text{ }\mu\text{g}$ of Be/m^3 . The DWA is based on area samples for the entire shift rather than a time-weighted average over a specific time period within the workshift. This rather drastic reduction in exposure concentrations sharply reduced the number of new cases of acute beryllium disease. In order to collect pertinent medical data for study and evaluation, the US Beryllium Case Registry (BCR) was initiated in 1952 [27].

Further study of CBD noted that the workers were generally exposed to the metal or other insoluble forms of beryllium over a long period of time [2]. Once the disease was diagnosed, only mild forms of the disease resolved after removal from exposure [22]. Workers may develop symptoms of CBD but often a latent form suddenly develops several years after the last exposure [17] and is usually fatal unless treated. The etiology of CBD was confusing to clinicians and toxicologists as some beryllium plants had high concentrations, but the workers were relatively free of CBD [3]. In other plants, the workers were exposed to significantly lower concentrations, but often experienced a much higher incidence of CBD. Some of the confusing aspects of CBD were resolved when Hall *et al.* [28] noted that the surface area of insoluble beryllium particles determined the toxic response, i.e., the greater the surface area, the greater the toxicity. This did not help resolve the enigma of a latent form of the disease. The latent form of the disease was not resolved until clinicians and toxicologists began to consider an immune mechanism for CBD.

The very first beryllium epidemiology study did not deal with beryllium workers, but instead involved 10 000 individuals residing within 2 miles of beryllium plants [29, 30]. Eleven neighborhood cases

of CBD were discovered *via* X-ray analysis. The ambient 24-h concentration was estimated to range between 0.05 and $0.2\text{ }\mu\text{g}$ of Be/m^3 . In a follow-up study, three additional cases within 0.75 miles of the plant were identified [17]. Beyond 0.75 miles, the average ambient air concentration was between 0.01 and $0.1\text{ }\mu\text{g}$ of Be/m^3 and no cases of CBD were found between 0.75 and 2 miles from the plant. On this basis, $0.1\text{ }\mu\text{g}$ of Be/m^3 was considered the no-observed-adverse-effect level (NOAEL) for the development of CBD. A total of 60 neighborhood cases of CBD were reported within 0.75 miles of a beryllium plant by 1966 [31]. Similar results were noted in residents near plants in Pennsylvania [32, 33]. These nonoccupational, low-exposure level cases along with a number of cases among secretaries at plants or others with light exposure suggested that a small percentage of the population can be sensitized to beryllium [34].

Sensitization has been confirmed in animal studies [35, 36] and in a number of epidemiology studies [37–41]. A major step forward in the diagnosis of CBD was the development of a beryllium lymphocyte proliferation test (LPT) [22, 42]. In the Kriess *et al.* [41] study, LPT was performed by two independent laboratories on samples collected from 136 employees. Five workers had positive LPT results from both laboratories and were diagnosed as having CBD on detecting granulomas in lung biopsy samples. Two other workers had abnormal LPT but no granulomas were found in biopsy samples. At least one of these two employees developed clinical signs of CBD within 2 years. Another worker developed a skin granuloma and had abnormal LPT. This worker developed lung granulomas within 2 years. Only one of these cases of CBD had abnormal chest X rays. A total of 11 out of 573 former workers had confirmed cases of CBD bringing the total incidence to 19/709. After considerable analysis of exposure levels, the lowest level producing CBD was estimated to be $0.55\text{ }\mu\text{g}$ of Be/m^3 . Based on ambient air concentration data, the NOAEL for sensitization was estimated to be between 0.01 and $0.1\text{ }\mu\text{g}$ of Be/m^3 [29].

In the studies that followed, it gradually became clear that CBD is an immunological disease or hypersensitivity reaction. Beryllium-sensitized cells accumulate to form granulomas in the lung [43–45]. All CBD cases that have progressed to the granulomas stage have a cell-mediated immune response

to beryllium [43, 44], and treatment that controls the immune response controls CBD [46]. Specific antibodies to beryllium have been identified [47]. Although variable results were seen with the blood LPT, the findings of the lung LPT (lymphocytes obtained *via* lung lavage) has been consistently positive in CBD patients [43, 44]. Improvements in the blood LPT, i.e., the use of tritiated thymidine, led to a much more reliable test [43, 48]. While the LPT has been extremely useful, a recent evaluation of the LPT in a long-term surveillance program [49], cautions against the reliability of a single LPT result. Multiple tests over weeks or months are considerably more reliable.

It is interesting to note that the incidence among workers exposed to 2–25 μg of Be/m^3 is about the same as past exposures to much higher levels ($>25 \mu\text{g}$ of Be/m^3) [17]. The TLV of 2 μg of Be/m^3 was first proposed in 1955 and adopted in 1959 [50, 51]. Occupational Safety and Health Administration (OSHA) adopted the level of 2 μg of Be/m^3 in 1971 [52]. This level was expected to eliminate the development of CBD in the workforce and while the number of new cases was reduced, CBD was not eliminated [24]. None-the-less, the BCR was eliminated in the 1980s. Of the 846 registered cases, 224 were of acute beryllium disease that resulted in 93 deaths [34]. Of the 622 CBD cases, 557 were due to occupational exposure, 42 due to neighborhood exposure, and 23 due to household exposure *via* handling contaminated clothing. The fact that beryllium is a sensitizer led the American Conference of Governmental Industrial Hygienists ACGIH [53] to recommend reducing the TLV from 2 to 0.2 μg of Be/m^3 in 2004, adding a sensitizer and a skin notation. The recommended level was lowered to 0.05 μg of Be/m^3 in 2006, with a short term exposure limit (STEL) of 0.02 μg of Be/m^3 [9, 54].

The last aspect of beryllium toxicity to surface was lung cancer. Early studies of the beryllium cohort were negative for cancer [31, 55, 56]. However, in workers with short-term exposure to beryllium, six out of eight lung cancer patients had recovered from a previous episode of acute beryllium disease [26]. More recent epidemiology studies have reported increased cancer rates for beryllium workers beginning in 1979 [57–59] with a follow-up in 1992 study [60]. In 1980, Infante *et al.* [61] studied the entrants to the BCR with a follow-up

study in 1991 [62]. As a result, the International Agency for Research on Cancer [63] stated that there is “limited evidence” that beryllium causes cancer in humans, but this was later changed to “sufficient evidence” that beryllium causes cancer [64]. Beryllium was first listed as “reasonably anticipated to be a human carcinogen” in the 2nd Annual Report on Carcinogens [65] and was later listed as “a known human carcinogen” in the 10th Report on Carcinogens [66]. In 1998, EPA identified beryllium as a “probable” human carcinogen in IRIS [4].

Animal Toxicity

Animal bioassays of beryllium were first conducted in 1946 as part of the Manhattan Project and only after several studies of health effects in humans had been reported [3]. Since that time, animal studies have confirmed many of the effects seen in worker populations.

In acute studies, soluble beryllium compounds are quite toxic *via* inhalation with 4-h LC_{50} 's ranging from 0.15 mg of Be/m^3 in the rat to 4.2 mg of Be/m^3 in the guinea pig [67]. Inhalation of insoluble forms is less acutely toxic than soluble forms.

Exposure of Fischer rats to 800 mg m^{-3} (800 000 $\mu\text{g m}^{-3}$) for 50 min produced effects in 14 days that resembled acute beryllium disease as seen in humans, including necrotizing, hemorrhagic exudative pneumonitis and alveolar fibrosis [68]. Eventually, foreign body granulomas were formed, but not similar to the granulomas as seen in the immune mechanism of CBD. Exposure to 0.013 mg m^{-3} (13 $\mu\text{g m}^{-3}$) [69] induced hyperplasia and infiltration of macrophages. Infiltrates of lymphocytes were not present [70] and the response resolved within 3 weeks postexposure.

Sensitization leading to granuloma formation was not seen in inhalation studies using soluble salts of beryllium in rats (Hart *et al.* [71]) or in mice [72]. Some aspects of CBD were seen in guinea pigs [73], beagle dogs [36, 74], and cynomolgus monkeys [74]. Evidence of a lymphocyte accumulation in the lungs of rats exposed to 1–100 mg m^{-3} (1000–100 000 $\mu\text{g m}^{-3}$) for 30–180 min [75]. Unfortunately, most animal inhalation studies involve liquid aerosols of soluble salts, e.g., Schepers *et al.* [76] rather than dust aerosols of insoluble forms

Table 1 Dose–response data based on beryllium epidemiology studies

Exposure level (μg of Be/m^3)	Results	References
0.01–0.1	No effect level for human exposure to airborne beryllium.	[17, 29]
0.05–0.2	Sensitization in susceptible individuals; CBD may develop in sensitized individuals upon continued exposure to $0.5\text{--}2.0\mu\text{g m}^{-3}$.	[17, 85]
2.0–28.4	No effect in nonsensitized workers; 6/146 sensitized workers exposed to $2\mu\text{g}$ of Be/m^3 developed CBD.	[24, 34]
5–100	Many early cases of CBD resulted from exposure to high levels of insoluble forms. Particles with large surface area are more potent than smaller particles.	[1, 2, 28]
>25 (peaks to 1310)	31/214 had chest X-ray abnormalities which resolved within 3 years after levels were reduced below $25\mu\text{g m}^{-3}$. Some evidence that mild early stages of CBD may be reversible.	[86, 87]
25–100	2/19 workers exposed to soluble forms developed acute beryllium disease. Both recovered and did not develop CBD.	[24]
100–1000	Most workers exposed to soluble beryllium salts develop acute beryllium disease, sometimes after a single exposure to high levels ($1000\mu\text{g}$ of Be/m^3). The disease resolves except in workers with massive pulmonary edema.	[12, 17]

such as the metal or beryllium oxide, e.g., Wagner *et al.* [77].

Lung cancer was seen in chronic inhalation studies in rats [78–81] and in monkeys [77, 78, 82]. No increase in tumor incidence was noted in hamsters [77].

Dose–Response

EPA has reviewed the animal toxicity and human epidemiology literature for beryllium [4, 83]. In making risk calculations, EPA selected the Wagoner *et al.* [59] study as the principal study for determining cancer risk; the Kreiss *et al.* [41] and Eisenbud *et al.* [29] as the principal studies for determining the reference concentration (RfC); and the Morgareidge *et al.* [84] as the principal study for calculating the reference dose (RfD). Of these, only the Morgareidge *et al.* study [84] had suitable dose–response data (*see Dose–Response Analysis*).

ATSDR also reviewed the animal toxicity and human epidemiology literature for beryllium [1, 2]. No inhalation minimum risk levels (MRLs) were calculated because the acute beryllium disease and CBD seen in animals did not totally mimic the disease

states seen in humans. For the chronic inhalation MRL, ATSDR did not accept the Eisenbud study [29] as a NOAEL for CBD.

While epidemiology data are often weakened because long-term, individual exposure levels in all job classifications are not readily available, the exposure data for beryllium has been reviewed rather closely and the dose–response data (Table 1) are presented as follows:

Exposure Assessment

The current environmental and hygienic standards for beryllium are as follows:

$$RfD = 0.002\text{ mg kg}^{-1}\text{ day}^{-1} \text{ [4].}$$

$$RfC = 0.02\mu\text{g m}^{-3} \text{ [4]}$$

$$TLV = 2\mu\text{g m}^{-3} \text{ with a notice to change to } 0.05\mu\text{g m}^{-3} \text{ [54]}$$

The RfD is considered a safe daily intake for the most sensitive members of the population. Similarly, the RfC is considered to be a safe concentration in the ambient air, i.e., safe even for the most sensitive in the population to breathe

continuously everyday. Ideally, the TLV is a safe time-weighted average concentration for the most sensitive members of the workforce to breathe for up to 8 h day⁻¹, 40 h wk⁻¹ but, by definition, it is meant to protect “nearly all of the exposed worker population”.

Almost all exposure will be limited to occupational exposure once the recommended TLV takes effect. In most regions of the United States, the ambient air beryllium concentration is below the level of detection of 0.03 ng m⁻³ [2]. Currently, urban areas have higher levels primarily due to the burning of coal and fuel oil [5]. Between 1982 and 1992, the annual ambient air concentration of beryllium was between 0.02 and 0.2 ng m⁻³ in Detroit (ATSDR [2]). In areas near beryllium processing plants, the ambient air concentration has been as high as 0.2 µg m⁻³ [29]. When the recommended TLV of 0.05 µg m⁻³ becomes effective, one could expect the neighborhood ambient air concentration to drop below 0.001–0.005 µg m⁻³ (1–5 ng m⁻³) within 0.75 miles of the plant and below 1 ng m⁻³ beyond 0.75 miles. Since sensitization is the critical effect and a NOAEL was reported as 0.01–0.1 µg m⁻³ (10–100 ng m⁻³), levels of 1–5 ng m⁻³ are not expected to affect the most sensitive members of the population.

A possible exception to this could be a worker, e.g., a jeweler working alone, who is not aware of the beryllium concentrations generated in his shop. Some hobbies, e.g., maintenance of the brakes on a private plane, could also result in inhaling beryllium dust. Beyond these types of possible exposure scenarios, the members of the general population will be exposed at levels well below the RfC.

Risk Characterization

EPA has calculated an RfD, an RfC, and a cancer unit risk for beryllium [4]. These levels are as follows:

$$RfD = 0.002 \text{ mg kg}^{-1} \text{ day}^{-1}.$$

$$RfC = 0.02 \text{ } \mu\text{g m}^{-3}.$$

$$\text{Cancer unit risk (q1*)} = 2.43 \text{ } \mu\text{g}^{-1} \text{ m}^{-3}.$$

ATSDR did not calculate any inhalation MRLs because their reviewers were: (a) not convinced that 0.1 µg m⁻³ was a NOAEL for sensitization because the latest detection techniques for sensitization were

not available in 1949; and (b) the acute and chronic forms of beryllium disease seen in animals does not totally mimic the diseases seen in humans. ATSDR did calculate a chronic oral MRL as 0.002 mg⁻¹ kg⁻¹ day⁻¹ [2].

Asset–Liability Management for Life Insurers

Asset–liability management or asset–liability modeling (ALM) for a life insurer is a quantitative approach to assessing risks in both the liabilities and the assets and developing risk-management strategies incorporating asset allocations, capital provisions, derivatives, and reinsurance. An important objective is ensuring asset cash flows meet liability cash flows over long terms. ALM for a life insurer requires valuation and projection of complex cash flows contingent on a wide range of risks including human mortality, sickness, interest rates, equity returns, inflation, and exchange rates. With the increase in computing power, ALM has become a powerful risk assessment technique for life insurers.

Products and Risks of Life Insurers

Life insurance companies provide coverage for risks related to human mortality, survival, as well as health and disability. They pool large numbers of life insurance risks (*see Copulas and Other Measures of Dependency*) and as a result benefit from the law of large numbers in the variability and prediction of expected future claim payments. They also issue contracts that provide a long term savings benefit linked to mortality risks. Life insurance contracts are for long terms (*see Fair Value of Insurance Liabilities*) compared to nonlife insurance. They involve guarantees to make payments for many years in the future. Whole of life insurance and annuities involve payments depending on death or survival for as long as the oldest age of survival of the lives insured. This is the ultimate age in the life table for risk modeling purposes. For example, an annuity could involve a commitment to make payment to an age of 120 in the case of a life annuity. Obviously, such occurrences are relatively rare events, but improvements in mortality and also pandemics can impact mortality risk across a range of ages. Term insurance contracts provide cover for periods as long as twenty or thirty years. Long term savings products usually have terms of at least 10 years.

Life insurance contracts can be participating with-profits, with a bonus payable on a regular basis depending on the surplus arising on the insurance business (*see Bonus–Malus Systems*). Once the bonus is paid it becomes a guaranteed part of the life insurance contract, adding to the obligations of the company. Bonuses may also be paid on maturity or termination of the contract, in which case they are referred to as *terminal bonuses*. For nonparticipating contracts the payments are mostly fixed or linked to an index such as the consumer price index (CPI) in the case of indexed annuities. The amount of the payment can be estimated with a high degree of confidence. For a large number of lives insured, the expected claims payments on death or survival can be estimated. Mortality improvements can cause some uncertainty in the estimate of future payments, but an allowance is usually made for this.

Even though the policies are issued for long terms, in many cases, the policies terminate owing to lapse or surrender prior to the maturity date of the policy. A policy lapses when a policyholder does not pay the premium and no contractual payment is owed to the policyholder. A policyholder can also surrender their policy prior to the maturity date of the policy and receive a payment on the policy. This payment is called the *surrender value*. Often the surrender value is guaranteed. A minimum surrender value is usually required by life insurance law in many countries. Maturity benefits on savings products and also death benefits on life insurance contracts may also be guaranteed in the form of an investment guarantee. For example, a guarantee on a life insurance policy could be a minimum benefit of a return of premiums with a specified and fixed interest rate in the event of death or surrender after a minimum term. This is often a requirement of life insurance legislation in many jurisdictions. Guarantees in life insurance policies have the same features as financial option contracts such as puts and calls although they are far more complex since they depend on investment returns as well as mortality and withdrawals and extend over very long terms.

Lapses and surrenders are hard to forecast because they can depend on future economic conditions. For example, if there is a recession, then policyholders with savings policies may need to surrender the policies to access their savings to cover short-term needs. If earnings rates offered on competitor savings

products are higher, then this can also lead to surrenders of these policies.

Life insurance companies receive premiums from policies and invest these funds in assets in order to satisfy claim payments as and when they fall due. Assets include short-term cash investments, fixed interest securities, shares, and property investments, as well as various alternative investments such as hedge funds and insurance linked securities. They also insure their own risks by purchasing reinsurance (*see* **Reinsurance**) from specialist reinsurance companies.

ALM for Interest and Mortality Risk

Penman [1] noted the problems that arise in asset–liability management for life insurers resulting from too generous guaranteed surrender values. He also noted the increased importance of currencies, commodities, inflation, and income tax in asset–liability management in the early 1900s. He discussed the idea of matching the currency of the assets and the currency of the life insurance contracts and the role of property and ordinary shares in matching inflation. The importance of diversification by geographical area and type of security was also recognized. C. R. V. Coutts, in the discussion of the Penman paper, introduced an asset–liability management strategy known as *matching*, by which he meant holding investments that were repayable at a time to cover contract payments from the fund over the following forty or fifty years.

However, it was Redington [2] who developed the principle of immunization of a life insurance company against interest rate movements. Assets were to be selected so that the discounted mean term or duration of the asset and liability cash flows were equal, and that the spread of the assets cash flows around their discounted mean terms, referred to as convexity, should exceed the spread of the liabilities around their mean term (*see* **Statistical Arbitrage**). These ideas became the foundation of life insurer ALM for many years until the adoption of more advanced option pricing and modeling techniques following the Nobel prize winning work of Black and Scholes [3]. These risk modeling and assessment approaches have been extended in more recent years. The early ALM for life insurers was designed for interest rate risk management and fixed- interest or

interest sensitive assets and liabilities. As noted in Sherris [4], matching can be considered as a special case of asset–liability portfolio selection under risk and capital constraints for the life insurer. Panjer [5] covers ALM for interest rate risk and ALM portfolio selection of assets to allow for liabilities.

Modern ALM for life insurers extends beyond interest rate risk and measuring the duration of assets and liabilities to a broader range of risks that can adversely impact the financial performance of the company. Immunization techniques were developed for fixed cash flows whose values were dependent on interest rates. Modern option pricing models allowed these to be extended to interest sensitive cash flows.

Over the last decade or more, longevity has become an important risk to be assessed by life insurers, particularly for life annuity and pension policies. As individual life expectancy increases, the value of life annuities increases. Selecting assets to manage and match longevity risk is difficult since markets in long term securities are limited and there is only a limited market in mortality risk, unlike the markets for credit, interest rate and equity risk. Securitization is an increasingly important risk management technique in ALM for life insurers and mortality risk. The importance of mortality risk is highlighted by the rapidly growing collection of research related to this topic including ALM issues.

Quantifying Risks for Life Insurers

The financial risks of a life insurer are quantified using specialized ALM projection software to model and project both the assets and the liabilities. Since the liabilities consist of many individual policies, it is common to group those of similar type, such as term and whole of life insurance, as well as by age-group and other characteristics, to project the liability cash flows. Asset cash flows, including interest and dividends, as well as maturity payments are often projected for portfolios including shares, property, and fixed interest. The projections use an economic scenario generator that generates future distributions for interest rates, inflation, equity and property returns, and liability cash flows allowing for mortality, lapses, surrenders, and maturities, as well as the benefit guarantees.

Modern financial concepts and techniques from option and contingent claim valuation theory are

used to derive market consistent valuations of assets and liabilities by valuing projected cash flows on a risk adjusted basis. The models are also used to assess risk based capital and reinsurance requirements, both very important components of the risk management strategy of a life insurer by simulating future scenarios for the business and determining the scenarios where asset cash flows are insufficient to meet liability cash flows. Simulation (*see Value at Risk (VaR) and Risk Measures*) of future scenarios is commonly used in these projections, although the computational time taken to perform a complete ALM risk assessment requires the use of modern and fast methods of computation, including quasi-random numbers and other variance reduction methods that can produce accurate estimations with fewer scenarios.

Since most life insurance products contain guarantees to make future fixed or dependent payments, as well as other option features, standard cash flow projection techniques will not necessarily assess the risk in the cash flows, unless specific allowance is made for these options. Stochastic projections incorporating future random outcomes are essential in order to quantify adverse scenarios, which can often occur when policyholders exercise valuable options in their policies, and at the same time, options in the asset cash flows can have an adverse financial impact; for example, policyholders who exercise surrender options when interest rates are high and there are valuable alternative investments, and at the same time asset values drop. The actual valuation of life insurer obligations allowing for the guarantees and options will usually substantially exceed the value ignoring these options. ALM can be used to project the outcomes where the life insurer is most at risk and to also quantify the cost of managing or reducing the risk.

Dynamic modeling, including stochastic optimization, has the potential to improve the risk assessment and management of life insurers. These techniques

are used increasingly in ALM for nonlife insurers (*see Numerical Schemes for Stochastic Differential Equation Models; Continuous-Time Asset Allocation; Bayesian Analysis and Markov Chain Monte Carlo Simulation; Optimal Stopping and Dynamic Programming*). The long term nature of life insurance cash flows presents new challenges for the application of these techniques.

Conclusion

ALM is a critical component of a quantitative risk assessment for financial performance; it ensures that a life insurer can meet policy obligations. Risk assessment modeling has developed over a number of years to highly sophisticated cash flow projection and valuation models incorporating modern developments in financial risk modeling and valuation. A detailed coverage of many of these techniques is found in Ziemba and Mulvey [6].

MICHAEL SHERRIS

Asset–Liability Management for Nonlife Insurers

In insurance, *asset–liability management* (ALM) is often treated as synonymous with *duration matching*. Matching refers to establishing and maintaining an investment portfolio – typically fixed income – that has the same average duration or even the same cash flow timing as the liability portfolio. The aim of a matching strategy is to protect the net value of the firm from interest rate changes, so that they affect the discounted values of assets and liabilities equally. Modern *enterprise risk analysis* (see **Enterprise Risk Management (ERM)**) and management provides the tools to design an investment strategy that reduces risks beyond interest rate hedging.

We define ALM to be a comprehensive analysis and management of the asset portfolio in light of current liabilities and future cash flows of a going-concern company, incorporating existing asset and liability portfolios as well as future premium flows. Besides duration matching, ALM considers additional risk factors beyond interest rate changes such as inflation risk, credit risk, and market risk. ALM also considers actions beyond the characteristics of a fixed income portfolio and seeks to identify and exploit hedges of any sort. For example, equities or real estate may provide a partial hedge against inflation-sensitive liabilities, at least over a long-enough time frame. *Reinsurance* (see **Reinsurance**), in this context, is a form of a hedge.

An example is foreign exchange risk. A typical hedging strategy is to keep assets in each currency equal to the liabilities, including unearned premiums. This is effective when the liabilities are known, but when they are random variables the mean of the liabilities might not be the proper target to hedge. Keeping some portion of capital in each currency might help reduce foreign exchange risk, and enterprise-wide, internal capital modeling can help evaluate the risk impact as part of an enterprise risk-management (ERM) program.

Insurance companies can benefit from the discipline of a more integrated analysis of the asset and liability portfolios in seeking better risk-return decisions. An enterprise-wide analysis of potential

risks and rewards affords an ideal opportunity to analyze the company's investment portfolio and underwriting portfolio in concert. Since insurance liabilities are far less liquid than assets, such analysis and management activity tend to focus on adjustments to the investment portfolio, given the constraints of the reserves and underwriting portfolio, to improve the risk-return characteristics of, say, annual earnings or a terminal (future) value of surplus. In this respect assets can be thought of as a way to hedge liability risk. However, management activity need not be confined to fine-tuning investment strategy. Future underwriting considerations, along with other hedges such as reinsurance, are risk-management variables at their disposal.

Venter *et al.* [1] presented a series of simple numerical examples illustrating that the optimal risk-return portfolio decisions are very different as the asset and liability considerations become more realistic and complex. The authors started with a stand-alone asset portfolio, then in a series of adjustments added a constant fixed duration liability, a liability that varied as to time and amount, and then added consideration of cash flows from current underwriting. As the various layers of complexity are added to the illustration, the nature of the inherent risks changes, as does the optimal investment portfolio:

- Looking at assets in isolation, short-term treasuries are considered risk-free, while higher yielding assets – stocks and bonds – are considered riskier. Traditional portfolio analysis would look at combinations of assets and measure their expected mean and variance, plotting return versus risk and searching out alternatives on an efficient frontier.
- Venter *et al.* point out that, when fixed liabilities are considered, holding shorter-term (that is, shorter than the liabilities) assets creates a new risk – a reinvestment risk. If interest rates drop, total investment income may prove insufficient to cover the liabilities. If interest rates increase, longer-term investments, too, present a new risk, if depressed assets need to be liquidated to fund liabilities. The risk to net assets, or surplus, can be reduced by cash flow matching. However there is a risk-return trade-off, as longer bonds usually have higher income. The accounting system in use may hide some of the risk as well.

- Adding in the complexity of liabilities that are variable as to amount and timing of cash flows makes precise cash flow matching impossible or transitory at best. Inflation-sensitive liabilities add additional complexity. A model incorporating both asset and liability fluctuations over time is required at this point to seek out optimal investment strategies.
- To make matters more difficult still, Venter *et al.*, introduce the notion of a company that is a going concern, with variable (positive or negative) cash flow from underwriting. Going concerns have greater flexibility. If, for example, conditions for liquidation are unfavorable, the company could pay claims from premium cash flows. At this level of complexity, an enterprise-wide model is truly needed, because, in addition to asset and liability models, a model of the current business operation is needed, including premium income, losses (including catastrophic losses), expenses, etc.

Venter *et al.*, did not address tax considerations, which can also have a profound impact on investment decisions. Recent studies have found that insurers consider cyclical changes in the investment portfolio between tax-exempt and taxable fixed income securities over the course of the underwriting cycle to be one of the principle drivers in investment strategy (as underwriting losses absorb taxable investment income). In addition to the integration of underwriting and investment results, such strategies rely on reallocation of assets to maximize income while avoiding alternative minimum taxes (AMT).

Little has been said up to this point about equity investments, but consideration of equities, too, adds some complexity and richness to the asset–liability analysis. Equities are considered risky in their own right and will imply a potentially worse downside risk to capital. Some believe that equities may provide a better inflation hedge for liabilities in an increasing loss cost environment. This proposition may be tested through the enterprise risk model, although the conclusion will be sensitive to input assumptions of the incorporated macroeconomic model.

In 2002, the Casualty Actuarial Society Valuation, Finance, and Investment Committee (VFIC) published a report [2] testing the optimality of duration matching (between assets and liabilities) investment strategies for insurance companies. To address this question, VFIC applied a simulation model to a

variety of scenarios – long-tailed *versus* short-tailed (with cat exposure), profitable *versus* unprofitable, and growing *versus* shrinking business. In doing so, VFIC attempted to tackle Venter’s most complex scenario discussed above.

Where Venter *et al.*, focused on changes in GAAP pretax surplus changes as the risk measure, VFIC looked at several different risk measures on both a statutory and a GAAP basis. Return, too, was considered on both accounting bases. In doing so, VFIC’s conclusion as to optimality was what one might expect in the real world: it depends. In fact, duration matching was among a family of optimal strategies, but the choice of specific investment strategies was dependent on the company’s choice of risk metrics, return metrics, and risk-return tolerances or preferences:

- Statutory accounting-based metrics implied little hedge from duration matching, as bonds were amortized and liabilities were not discounted.
- GAAP accounting-based metrics resulted in similar conclusions: though bonds were marked to market, there was no hedge to the liabilities.
- If metrics are calculated based on “true economics”, that is with bonds marked to market and liabilities discounted at current market rates, matching produces a low interest rate risk. In this case, a short investment strategy increases risk (creates mismatch in duration) and decreases return. Longer-duration investment strategies increase risk and return, making the trade-off more of a value judgment. In the economic case, the introduction of cash flows from operations greatly complicated the analysis and conclusions. However, this analysis did not consider the impact of inflation-sensitive liabilities.

An Asset–Liability Modeling Approach

It has been asserted earlier that an enterprise-wide model is the ideal, perhaps the only, way to model and ultimately manage an insurance company investment portfolio. ALM makes for an excellent application of such an integrated model.

The introductory comments highlight a series of modeling steps and management considerations that supply the necessary structure to the analysis of an insurer’s investment portfolio, given the liabilities it supports.

1. Start with models of asset classes (stocks, bonds, real estate, commodities), existing liabilities (loss reserves, receivables), and current business operations.
2. Define risk metric(s) for the analysis. Consideration should be given to accounting basis – statutory, GAAP, or economic. Risk can be defined on the basis of the volatility of periodic income or the volatility of ending surplus or equity. Decisions are therefore also necessary as to the time frames of the analysis (*see Axiomatic Measures of Risk and Risk-Value Models*).

Examples of risk metrics – either income based or balance sheet based – include the standard deviation and the probability of falling below a predetermined threshold. Balance sheet (surplus or equity) measures are more amenable to other metrics as well, such as value at risk, tail value at risk, *probability of ruin* (*see Ruin Probabilities: Computational Aspects*), or probability of impairment.

3. Similarly, management must define what constitutes “return”. Again, consideration must be given to accounting basis, and clearly risk and return must be defined in a compatible fashion. Return, too, can be income based or balance sheet based. For example, return can be periodic earnings or return on equity (ROE) (income measures), or it can be a terminal value of surplus (balance sheet).
4. Consideration must be given to the time horizon of the analysis and the relevant metrics. Single-period models are perhaps simpler, but may not adequately reflect the true nature of the business throughout a cycle. Multiperiod models can be more sophisticated – but also more difficult and complicated – especially if cycles and serial correlations are incorporated throughout.
5. The model will have to consider relevant constraints. For example, constraints might include limits on asset classes imposed by state regulators, or investments that drive rating agency or regulatory required capital scores too high, or restrictions based on the company’s own investment policy.
6. The model should be run for a variety of investment strategies, underwriting strategies, and reinsurance options under consideration. For each combination of scenarios, there will be thousands

of realizations. The selected risk and return metrics are calculated over these simulations.

7. An efficient frontier – a plot of the return metric versus the risk metric – can be constructed across the various portfolio scenarios (*see Figure 1*). The point in the risk-return space that defines the current portfolio should be represented. Portfolio moves should be explored where risk can be decreased without sacrificing return (A), where return can be increased without increasing risk (B), and points in between (C). Points on the frontier are considered optimal combinations of returns for given levels of risk. While a point on the curve should be an investment portfolio goal for the company, the selection of one point over another is dependant on the company’s preferences as defined by risk tolerances and return requirements.
8. It was noted at the outset of the process description that, since liabilities are more illiquid, the asset-liability analysis and management can be largely asset centric given the existing liabilities. The nature of the liabilities, however, can be adjusted – risks can be hedged – through reinsurance purchases. The effects of such purchases can have profound impacts on an ALM analysis, especially in a multiperiod model.

Various reinsurance structures should be modeled with the alternative asset portfolio options and the results compared. For example, Figure 2 compares the results of reinsurance and asset allocation decisions in the worst 1% of the simulations over time. The vertical axis represents company surplus, and the horizontal axis represents time. In this particular example, the analysis

Figure 1 Efficient frontier

Figure 2 Reinsurance and asset allocation metrics

was conducted over a 3-year window. Beyond the gross (no reinsurance) option, the second and fourth options show better and more stable ending surplus values in the worst 1% of the simulations.

9. Having selected a targeted point on an efficient frontier and a companion reinsurance strategy, simulation output should be analyzed to identify those scenarios where even the preferred portfolio(s) performed poorly (since Figures 1 and 2 are drawn only at single points on the distribution of possible results). It is possible that an asset hedging strategy can be employed to reduce downside risks. It may also be the case that further investigation will highlight the type of prevailing conditions that can lead to substandard performance, for example, a large catastrophe that forces liquidation of assets, or a persistent soft market. Management can establish policy and monitoring mechanisms to identify the existence or the likelihood of such conditions and make appropriate adjustments.

Future Research

While enterprise-wide modeling is perhaps the only way to adequately address asset–liability management issues, there are a number of real-world issues that are subject of continuing research. For example, correlations among lines of insurance (either in current business or in past reserves), between assets and liabilities, and over time are poorly understood today.

And yet correlations can materially alter the risk of the optimal portfolio. Also, models of unpaid losses, while they can derive expected values and distributions, have not been developed as explanatory models. That is, unlike asset models, reserving models do not predict future loss payments with parameters linking losses to economic indices. Inflation sensitivity is often hypothesized on an accident year, a calendar year, or a payment year basis, but rarely explicitly developed from historic economic data and projected on the basis of, say, an economic scenario generator.

Association Analysis

Association analysis aims to determine whether a *disorder* of interest correlates with *genetic variation* in the population. Such a correlation indicates that either the surveyed genetic variation predisposes to disease or acts as a proxy for the causal variant (see the section titled “Linkage Disequilibrium”). In this article, we provide a short introduction to association at a conceptual level, both analytically and genetically. Next we consider the two primary association approaches for mapping disease loci – case–control and family-based studies. The article concludes with recent developments in association, such as genome-wide association (GWA) that hold great promise for mapping of genetic variation related to common disease.

Conceptual Underpinnings

For association analysis to be conducted, a direct assay of genotypic variation (i.e., to know the genetic code at the locus of interest for all individuals in the analysis) is typically required. While many types of genetic variation exist in the human genome, the most commonly assayed for association are single nucleotide polymorphisms (SNPs). SNPs are composed of two *alleles* (forms) within the population. Given that humans are diploid (i.e., their chromosomes are organized in pairs, having inherited one of each pair from their mother and the other from their father), every individual has two copies of the SNP at a locus; this pair of SNPs constitutes the *genotype* at that locus. For didactic purposes, we restrict our considerations to SNPs, but the association techniques presented have been extended to genetic loci at which there are multiple alleles (e.g., microsatellites [1]).

Considering a SNP marker with two alleles (labeled A_1 and A_2), there are three possible genotypes (A_1A_1 , A_1A_2 , and A_2A_2). The genotypes with two copies of the same allele (i.e., A_1A_1 and A_2A_2) are termed *homozygotes* and the genotype with a copy of each allele is termed the *heterozygote* (A_1A_2). Given a sample of genotypes from a population of interest, it is possible to estimate the proportions of the alleles A_1 and A_2 (which are typically labeled p and q , respectively, with $q = 1 - p$), as well as the proportions of the genotypes A_1A_1 , A_1A_2 ,

and A_2A_2 . The terms *allele frequency* and *genotype frequency* are in common use for these quantities in genetics, and this convention will be used here. The expected frequencies for the genotype categories may be derived by assuming Hardy–Weinberg equilibrium (HWE), which occurs when mating in the population is random and the genotypes are equally viable [2, 3]. These expected frequencies are p^2 , $2pq$, and q^2 for A_1A_1 , A_1A_2 , and A_2A_2 , respectively. Testing for a deviation from HWE provides a good check for the quality of the genotype information and evidence for confounding or assortative (nonrandom) mating. However, HWE tests are usually restricted to controls, because deviation from HWE is conflated with true association signal in cases [4].

Case–Control Association Tests

With the genotype information available, it is possible to define a range of association tests for cases and control subjects. Much like any comparison between cases and controls, for a discrete predictor, a one degree of freedom Pearson’s χ^2 test on allele counts may be calculated from the data organized in Table 1.

Let the rows of Table 1 be indexed by i (where $i = 1$ represents cases and $i = 2$ represents controls), and the columns of by j (where $j = 1$ corresponds to A_1 and $j = 2$ corresponds to A_2). Then χ^2 is then calculated as:

$$\chi^2 = \sum_{i=1}^2 \sum_{j=1}^2 \frac{(N_{ij} - M_{ij})^2}{M_{ij}} \quad (1)$$

where: N_{ij} is the allele count in row i , column j of Table 1; and M_{ij} is computed as the product of the sum of the elements in row i and the sum of the elements in column j , divided by N_{total} ($M_{ij} = N_{i*} * N_{*j} / N_{\text{total}}$, where $N_{*j} = N_{1j} + N_{2j}$; $N_{i*} = N_{i1} + N_{i2}$). It is also possible to calculate a two degree of freedom Pearson’s χ^2 from a table of genotype counts instead of allele counts.

The allelic test effectively employs an additive model, whereas the genotype test is saturated, because the three genotype categories are specified separately. It is also possible to use the information in Table 2 to estimate the odds ratio (see **Odds and Odds Ratio**) or increase in disease risk conferred by the risk allele in cases as compared to

Table 1 Notation for counts of alleles A_1 and A_2 in cases (d_1 and d_2 , respectively) and in controls (u_1 and u_2 , respectively)

	Allele counts		Total
	A_1	A_2	
Case	d_1	d_2	N_{case}
Control	u_1	u_2	N_{control}
Total	N_{A_1}	N_{A_2}	N_{total}

Table 2 Notation for counts of genotypes A_1A_1 , A_1A_2 , and A_2A_2 : $d_{11}d_{12}d_{22}$ are the respective genotype counts for cases, and u_{11} , u_{12} , and u_{22} are the corresponding genotype counts for controls

	Genotype counts			Total
	A_1A_1	A_1A_2	A_2A_2	
Case	d_{11}	d_{12}	d_{22}	N_{case}
Control	u_{11}	u_{12}	u_{22}	N_{control}
Total	N_{11}	N_{12}	N_{22}	N_{total}

controls:

$$OR = \frac{[(d_{12} + d_{22}) \times u_{11}]}{[d_{11} \times (u_{12} + u_{22})]} \quad (2)$$

The prevalence or the proportion of the population that is affected can be defined in terms of the *penetrance* of each genotype class:

$$K = p^2f_2 + 2pqf_1 + q^2f_0 \quad (3)$$

where K is the prevalence, p and q are the allele frequencies for A_1 and A_2 , respectively, and f_2 , f_1 , and f_0 represent the probability of expressing the trait for genotype categories A_1A_1 , A_1A_2 , and A_2A_2 . In the event of no association, $f_2 = f_1 = f_0 = K$ [5].

An alternative to these Pearson's χ^2 tests is to specify a logistic regression (*see Logistic Regression*) model for association analysis. For this regression model, the alleles for each individual are coded as an indicator variable, so the model is

$$\text{logit}(y_i) = \alpha + \beta x_i \quad (4)$$

where y_i is the case or control status, α is the intercept, β is the regression coefficient for the locus, and x_i is an indicator variable for the number of copies of A_2 . Note that only one of the two alleles is coded, because the second is linearly dependent upon

it (i.e., it is collinear). Essentially, this formulation specifies a multiplicative risk model for the effect of the allele in the population (i.e., the relative risk for genotype $A_1A_1 = R \times A_1A_2 = R^2 \times A_2A_2$).

An alternative approach is to parameterize the model so that the risk for each genotype is estimated directly:

$$\text{logit}(y_i) = \alpha + \beta_1 x_i + \beta_2 w_i \quad (5)$$

where y_i is the case or control status, α is the intercept, β_1 is the regression coefficient for A_1A_1 homozygote, x_i is an indicator variable coded 0/1 for the presence or absence of genotype A_1A_1 , β_2 is the regression coefficient for A_2A_2 homozygote, and w_i is an indicator variable coded 0/1 for the presence or absence of genotype A_2A_2 .

As noted, the first regression model follows a multiplicative genetic model, in that it is based on the number of alleles and does not consider the interaction between the alleles at the locus in question. However, it is possible to specify a model where the allelic effects operate according to a simple dominant or recessive mode of gene action. An allele is said to be dominant when only one copy of it is required for it to affect the phenotype; it is said to be recessive when two copies are required. Table 3 shows how models for dominant and recessive gene action may be parameterized.

In general, the regression models are preferable for association testing. Their main benefits are that (a) they are computationally efficient, (b) it is straightforward to incorporate other loci or covariates, and (c) it possible to test for interactions between the alleles at a locus, between different loci, or between covariates (such as environmental exposure) and alleles.

Table 3 Genotype frequency and penetrance patterns under different modes of gene action

	A_1A_1	A_1A_2	A_2A_2
Genotype frequency	p^2	$2pq$	q^2
Penetrance	f_2	f_1	f_0
Assuming recessive gene action	0	0	1
Assuming dominant gene action	1	1	0
Assuming multiplicative gene action	x^2	x	0

Population Stratification

One potential pitfall of the case–control study is population stratification or substructure. Between populations, allele frequencies tend to differ at a range of loci because of a phenomenon known as *genetic drift*. When such variation between populations is coupled with differences in the prevalence of a disease, spurious association may result. For example, consider the binary trait of “ever used chopsticks”. If cases and controls were sampled from a population consisting of American and Chinese individuals, then significant association would be likely to be found at any locus where the allele frequencies differ between these two groups [6]. This situation is illustrated in Table 4.

Locus A shows no association in either sample, yet there is highly significant association when the two datasets are combined and analyzed jointly. Also note that stratification might eliminate a genuine allelic effect, and cause a false negative finding. To control this particular problem, family-based association designs were proposed.

Family-Based Association

Unlike case–control designs for the identification of risk variants, family-based designs employ auto-control mechanisms. The first family-based design proposed was the transmission disequilibrium test (TDT), which utilizes Mendel’s law of segregation. The key principle is that the transmission of either allele from a heterozygous parent (i.e., genotype A_1A_2) is equally likely. However, affected offspring should be more likely to inherit risk alleles than non-risk. Thus, it is possible to test for overtransmission of risk variants using the McNemar χ^2 , as the transmission or nontransmission from heterozygous parents is a paired observation (see Table 5 and Figure 1).

Table 5 Transmission and nontransmission of alleles from heterozygous parents to affected offspring

	A_1	A_2
Transmission	t_1	t_2
Nontransmission	nt_1	nt_2

Note that $t_1 = nt_2$ and $t_2 = nt_1$

Figure 1 Example parent-offspring trio showing transmission of the risk allele

The test is computed using the formula

$$\chi^2 = \frac{(nt_1 - t_1)^2}{nt_1 + t_1} = \frac{(nt_2 - t_2)^2}{nt_2 + t_2} \quad (6)$$

Allele A_1 is transmitted from the heterozygous father to the affected daughter. If no association is present, A_1 and A_2 would have equal chance of transmission.

The TDT is robust to population stratification, because it only considers parents of a single genotype (i.e., heterozygotes).

Although the TDT may seem to be applicable only when parental genotypes are available, it is possible to use the same principle in the study of sibling pairs [7, 8]. Conceptually, if two siblings are discordant for the phenotype, then the affected sibling ought

Table 4 Demonstration of the effects of population stratification

Use of chopsticks									
	Sample 1 (Americans); $\chi^2 = 0, p = 1$			Sample 2 (Chinese); $\chi^2 = 0, p = 1$			Sample 3 (Americans + Chinese); $\chi^2 = 34.2, p = 4.9 \times 10^{-9}$		
A	Yes	No	Total	Yes	No	Total	Yes	No	Total
A_1	320	320	640	320	20	340	640	340	980
A_2	80	80	160	320	20	340	400	100	500
Total	400	400	800	640	40	680	1040	440	1480

to harbor more risk variants than the unaffected sibling. As the siblings are from the same parents, then they are *de facto* from the same stratum of the population. Thus, population stratification cannot be a problem. The basic test of significance for the sib-TDT employs a permutation test. The genotypes of a pair of sibships are randomly reassigned and the difference in marker allele frequencies between case and control siblings is tested. This procedure is repeated a large number of times to determine the empirical distribution of the test. Then, the true sample difference test statistic (i.e., when no randomization has been performed) is compared to the empirical distribution to determine its significance. The sib-TDT and the TDT information have been combined together into family-based association test [9–11] and the pedigree disequilibrium test [12].

Future Directions

Technologically, genetics is moving forward at an extremely rapid pace. Over the course of approximately the last decade, three main projects have pushed association analysis to the forefront of genetics: the Human Genome Project (HGP), The SNP consortium, and the international HapMap project (HapMap) [13, 14]. The HGP generated a consensus sequence, facilitating the SNP consortium the aim of which was SNP discovery. With a database of known SNPs, the HapMap project set out on identifying linkage disequilibrium (LD) information enabling further development of cost-effective genotyping platforms.

Linkage Disequilibrium

LD refers to the nonrandom distribution of alleles at two different loci. In effect, the genotype at one locus may be used to predict, to some extent, the genotype at the second locus [15]. This association between loci may be considered as a correlation between the alleles at two loci. A consequence of this correlation is that an association test conducted on a marker in LD with the causal variant will also show association. There are two main statistics for LD: D' [16]; and r^2 [17]. D' generally tracks with recombination rate, while r^2 is more appropriate for determining power for association. Both D' and r^2 aim to detect a deviation from the expected frequency of each haplotype (the allele at both loci

on the same strand of DNA) configuration from the product of the allele frequencies. Considered another way, these LD measures equal zero for a pair of loci (A_1/A_2 and B_1/B_2), when the probability of haplotypes $p_{A_1B_1} = p_{A_1} \times p_{B_1}$, $p_{A_1B_2} = p_{A_1} \times p_{B_2}$, $p_{A_2B_1} = p_{A_2} \times p_{B_1}$, and $p_{A_2B_2} = p_{A_2} \times p_{B_2}$.

A useful consequence of LD is that it is not necessary to type all variations across the genome to capture variation. In 2002, the HapMap project was launched as an international collaboration between the National Institutes of Health in the United States, Canada, Japan, China, the SNP consortium and the Wellcome trust [18]. Originally, the HapMap project aimed to identify and tag “haplotype blocks” that were observed across the genome [19]. Three populations were genotyped: an East Asian, comprised 45 unrelated Han Chinese individuals from Beijing and 45 unrelated Japanese individuals from Tokyo; a European, comprised 30 families of two parents and a single offspring from the *Center d'Etude du Polymorphisme Humain* (CEPH) collected in Utah; and a West African, comprised 30 families of two parents and a single offspring drawn from the Yoruba people of Ibadan, Nigeria.

Initially, HapMap had two main genotyping strategies for the three populations:

1. Densely type 10 “ENCODE” regions of 5 megabases (5 mb, 5000 base pairs) to gain insight into the fine-scale nature of the genome.
2. Genotype a SNP every 5 kb across the whole genome.

This genome-wide data provides a public resource for researchers interested in disease mapping. The HapMap project produced important new data in three principal areas: design and analysis of association studies, understanding human population history as shaped by mutation and recombination, and the illustration of global similarities and differences (www.hapmap.org). With the HapMap resource, it is now possible to tailor genotyping assays so that they capture all the common genomic polymorphisms at a fraction of the cost that would be required to type all the polymorphisms along the genome.

Differences between populations are potentially problematic for utilizing LD information [20, 21]. However, recent work has shown that population differences for LD are consistent with other variation

between populations. Broadly, continental groups can be considered jointly for the purposes of LD information with differences increasing with geographical distance [22–25].

The proportion of human genetic variation that needs to be captured for a study to be classified as a genome-wide association (GWA) scan is still a matter of debate [26]. Current SNP chip technology permits the assaying of approximately 1 million SNPs across the genome. Considering that in 2005, the first major success story of GWA was conducted using 100 K SNP chips, this rate of increase in density (an order of magnitude in 2 years) is dramatic. The first successful GWA identified a risk variant for age-related macular degeneration (AMD; certain variants in the complement factor *H* gene were demonstrated to predispose to the disorder) [27]. Since then, studies employing the 100 K SNP chips have identified variation in *NOS1AP* (also known as *CAPON*) that influences the QT interval on an electrocardiogram [28]. Importantly, both of these findings replicated significantly across a number of other studies and, as a result, are almost certainly true associations [28–33]. It seems likely that variants influencing many other conditions will be identified in future studies. Hopefully, these results in turn will lead to improved tests, treatments, and preventive measures for the major physical and psychological disorders with which so many people are afflicted.

Attributable Fraction and Probability of Causation

One often sees measures that attempt to assess the public health impact of an exposure by measuring its contribution to the total incidence under exposure. For convenience, we will refer to the entire family of such fractional measures as *attributable fractions*. The terms *attributable risk percent* or just *attributable risk* are often used as synonyms, although “attributable risk” is also used to denote the risk difference [1–3]. Such fractions may be divided into two broad classes, which have been called *excess fractions* and *etiologic fractions*. The latter class corresponds to the concept of probability of causation.

A fundamental difficulty is that the two classes are usually confused, yet excess fractions can be much smaller than etiologic fractions, even if the disease is rare or other reasonable conditions are met. Another difficulty is that etiologic fractions are not estimable from epidemiologic studies alone, even if those studies are perfectly valid. Assumptions about the underlying biologic mechanism must be introduced to estimate etiologic fractions, and the estimates will be very sensitive to those assumptions.

To describe the situation, imagine we have a cohort of initial size N , and we are concerned with the disease experience over a specific time period, which is at issue in relation to a particular exposure (e.g., to a chemical, drug, pollutant, or food). We wish to contrast the disease experience of the cohort under its actual exposure history with what the experience would have been under a different (counterfactual or reference) exposure history. Usually the actual history involves some degree of exposure for all cohort members, and the reference history would involve no exposure, although the latter may instead involve only a different degree of exposure from the actual level (as is typical in air-pollution research; see **Air Pollution Risk**). For simplicity we will call the actual exposure history *exposed* and the counterfactual history *unexposed*, although the discussion applies to more general cases.

The following notation will be used:

A_1 : number of disease cases occurring under the actual exposure history;

A_0 : number of cases occurring under the counterfactual (reference) exposure history;

$R_1 = A_1/N$: incidence proportion (average risk) under the actual exposure history;

$R_0 = A_0/N$: incidence proportion under the counterfactual exposure history;

T_1 : total time at risk experienced by the cohort under the actual exposure history;

T_0 : total time at risk that would be experienced by the cohort under the counterfactual exposure history;

$I_1 = A_1/T_1$: incidence rate under the actual exposure history;

$I_0 = A_0/T_0$: incidence rate under the counterfactual exposure history. Then $R_1/R_0 = RR$ is the risk ratio and $I_1/I_0 = IR$ is the rate ratio for the effect of the actual exposure history relative to the counterfactual exposure history [4].

Throughout, it is assumed that the counterfactual history is one that is precisely defined (a placebo treatment, or withholding all treatment), and could have occurred physically even though it may not have been ethical or affordable. Without some such constraint, the meaning of “cause”, “effect”, and hence causal attribution becomes unclear [5–7].

Excess Fractions

One family of attributable fractions is based on recalculating an incidence difference as a proportion or fraction of the total incidence under exposure. One such measure is $(A_1 - A_0)/A_1$, the excess caseload owing to exposure, which has been called the *excess fraction* [8]. In a cohort, the fraction $(R_1 - R_0)/R_1 = (RR - 1)/RR$ of the exposed incidence proportion R_1 that is attributable to exposure may be called the *risk fraction*, and is exactly equal to the excess caseload fraction:

$$\begin{aligned} \frac{R_1 - R_0}{R_1} &= \frac{RR - 1}{RR} = \frac{A_1/N - A_0/N}{A_1/N} \\ &= \frac{A_1 - A_0}{A_1} \end{aligned} \quad (1)$$

The analogous relative excess for the incidence rate is the *rate fraction* or *assigned share* $(I_1 - I_0)/I_1 = (IR - 1)/IR$ [8, 9]. This rate fraction is often mistakenly equated with the excess caseload fraction $(A_1 - A_0)/A_1$. To see that the two fractions are not

equal, note that the rate fraction equals

$$\frac{A_1/T_1 - A_0/T_0}{A_1/T_1} \quad (2)$$

If exposure has an effect and the disease removes people from further risk (as when the disease is irreversible), then $A_1 > A_0$, $T_1 < T_0$, and hence the rate fraction will be greater than the excess fraction $(A_1 - A_0)/A_1$. If, however, the exposure effect on total time at risk is small, T_1 will be close to T_0 and the rate fraction will approximate the latter excess fraction [8].

Etiologic Fraction

The *etiologic fraction* is the fraction of cases “caused” by exposure, in that exposure had played some role in the mechanism leading to a person’s disease. We can estimate the total number of cases, and so we could estimate the etiologic fraction if we could estimate the number of cases that were caused by exposure. Unfortunately, and contrary to intuitions and many textbooks, the latter number is not estimable from ordinary incidence data, because the observation of an exposed case does not reveal the mechanism that caused the case. In particular, people who have the exposure can develop the disease from a mechanism that does not include the exposure.

As an example, a smoker may develop lung cancer through some mechanism that does not involve smoking (e.g., one involving asbestos or radiation exposure, with no contribution from smoking). For such lung-cancer cases, their smoking was incidental; it did not contribute to the cancer causation. The exposed cases include some cases of disease caused by the exposure (if the exposure is indeed a cause of disease), and some cases of disease that occur through mechanisms that do not involve the exposure.

Unfortunately, there is usually no way to tell which factors are responsible for a given case. Thus, the incidence of exposed cases of disease caused by exposure usually cannot be estimated [8, 10]. In particular, if I_1 is the incidence rate of disease in a population when exposure is present and I_0 is the rate in that population when exposure is absent, the rate difference $I_1 - I_0$ does not necessarily equal the rate of disease arising from mechanisms that include exposure as a component, and need not even be close

to that rate. Likewise, the rate fraction $(I_1 - I_0)/I_1$ need not be close to the etiologic fraction.

As a simple example of the potential discrepancy, suppose our cohort has $N = 3$ persons given a surgical procedure (the exposure) at age 50, and the time period of interest is from that point for 40 years following exposure (through age 90). Suppose persons 1, 2, and 3 died at ages 60, 70, and 80 as exposed (thus surviving 10, 20, and 30 years past age 50), but would have died at ages 75, 85, and 90 had the exposure (surgery) not been given (instead surviving 25, 35, and 40 years past 50). As all the three cohort members had their lives shortened by the exposure, the etiologic fraction is 1, the largest it can be. However, we have $A_1 = A_0 = 3$, for a risk fraction of $(1 - 1)/1 = 0$. Also, $T_1 = 10 + 20 + 30 = 60$, and $T_0 = 25 + 35 + 40 = 100$, for $I_1 = 3/60 = 0.05$, and $I_0 = 3/100 = 0.03$, and a rate fraction of $(0.05 - 0.03)/(0.05) = 0.20$, far less than 1.

Despite the potentially large discrepancy, excess fractions and rate fractions are often incorrectly interpreted as etiologic fractions. The preceding example shows that these fractions can be far less than the etiologic fraction. Under mechanisms in which exposure accelerates the occurrence of disease (e.g., for tumor promoters), the rate fraction will be close to zero if the rate difference is small relative to I_1 , but the etiologic fraction will remain close to 1, regardless of A_0 or I_0 . The rate fraction and etiologic fraction are equal under certain conditions, but these conditions are not testable with epidemiologic data and rarely have any supporting evidence or genuine biologic plausibility [11–14]. One condition sometimes cited is that exposure acts independently of background causes, which will be examined further below. Without such assumptions, however, the most we can say is that the excess fraction provides a lower bound on the etiologic fraction.

One condition that is irrelevant yet sometimes given is that the disease is rare. To see that this condition is irrelevant, note that the above example made no use of the absolute frequency of the disease; the excess and rate fractions could still be near 0 even if the etiologic fraction was near 1. Disease rarity brings the risk and rate fractions closer to one another, in the same manner it brings the risk and rate ratios close together (assuming exposure does not have a large effect on the person time [4]). However, disease rarity does not bring the rate fraction close to the etiologic fraction, as can be seen by modifying

the above simple example to include an additional 1000 cohort members who survive past age 90 [10].

Probability of Causation

To further illustrate the difference between excess and etiologic fractions, suppose exposure is sometimes causal and never preventive, so that $A_1 > A_0$, and a fraction F of the A_0 cases that would have occurred with or without exposure are caused by exposure when exposure does occur. In the above simple example, $F = 1$, but is usually much smaller. A fraction $1 - F$ of the A_0 cases would be completely unaffected by exposure, and the product $A_0(1 - F)$ is the number of cases unaffected by exposure when exposure occurs. Subtracting this product from A_1 (the number of cases when exposure occurs) gives $A_1 - A_0(1 - F)$ for the number of cases in which exposure plays an etiologic role when it occurs. The fraction of the A_1 cases caused by exposure is thus

$$\frac{A_1 - A_0(1 - F)}{A_1} = \frac{1 - (1 - F)}{RR} \quad (3)$$

If we randomly sample one case, this etiologic fraction formula equals the probability that exposure caused that case, or the *probability of causation* for the case. Although of great biologic and legal interest, this probability cannot be epidemiologically estimated if nothing is known about the fraction F [8, 10–14].

Now suppose exposure is sometimes preventive and never causal, so that $A_1 < A_0$, and a fraction F of the A_1 cases that would have occurred with or without exposure are caused by nonexposure when exposure does not occur. Then the product $A_1(1 - F)$ is the number of cases unaffected by exposure; subtracting this product from A_0 gives $A_0 - A_1(1 - F)$ for the number of cases in which exposure would play a preventive role. The fraction of the A_0 unexposed cases that were caused by nonexposure is thus

$$\frac{A_0 - A_1(1 - F)}{A_0} = \frac{1 - (1 - F)}{RR} \quad (4)$$

As with the etiologic fraction, this fraction cannot be estimated if nothing is known about F [4].

Biologic and Societal Considerations

Excess fractions require no biologic model for their estimation. Thus, they can be estimated from epidemiologic data using only the usual assumptions about study validity and that the exposure does not change the population at risk. In contrast, estimation of the etiologic fraction requires assumptions about the mechanism of exposure action, especially in relation to sufficient causes that act in the absence of exposure. At one extreme, mechanisms involving exposure would occur and act independently of other “background” mechanisms, in which case excess and etiologic fractions will be equal. At the other extreme, in which exposure advances the incidence time whenever a background mechanism is present, the excess fraction can be tiny but the etiologic fraction will be 100% [10–14]. Both extremes are rather implausible in typical settings, and there is rarely enough information to pin down the etiologic fraction, even if the excess fractions are known accurately.

The distinction is of great social importance because of the equality between the etiologic fraction and the probability of causation. The confusion between excess fractions and the probability of causation has led to serious distortions in regulatory and legal decision criteria [10, 14]. The distortions arise when criteria based solely on epidemiologic evidence (such as estimated relative risks) are used to determine whether the probability of causation meets some threshold. The most common mistake is to infer that the probability of causation is below 50% when the relative risk is inferred to be below 2. The reasoning is that $(RR - 1)/RR$ represents the probability of causation, and that this quantity is below 50% unless RR is at least 2. This reasoning is fallacious, however, because $(RR - 1)/RR$ is the excess caseload fraction among the exposed. Thus it may understate the probability of causation to an arbitrarily large degree, in the same manner as it understates the etiologic fraction, even if the RR estimate is highly valid and precise [10–12].

Terminology

More than with other concepts, there is profoundly inconsistent and confusing terminology across the literature on attributable fractions. Levin [15] used the term *attributable proportion* for his original measure

of population disease impact, which in our terms is an excess fraction or risk fraction. Many epidemiologic texts thereafter used the term *attributable risk* to refer to the risk difference $R_1 - R_0$ and called Levin's measure an *attributable risk percent* [1, 3]. By the 1970s, however, portions of the biostatistics literature began calling Levin's measure an "attributable risk" [16, 17], and unfortunately part of the epidemiologic literature followed suit.

Some epidemiologists struggled to keep the distinction by introducing the term *attributable fraction* for Levin's concept [18, 19]; others adopted the term *etiologic fraction* for the same concept and thus confused it with the fraction of cases caused by exposure [20]. The term *attributable risk* continues to be used for completely different concepts, such as the risk difference, the risk fraction, the rate fraction, and the etiologic fraction. On account of this confusion, it has been recommended that the term *attributable risk* be avoided entirely, and that the term *etiologic fraction* not be used for excess fractions [8].

Availability and Maintainability

Modern-day industry has become more mechanized and automated. This trend has also enhanced the business risks associated with stoppages or nonfunctioning of equipments and other engineering systems deployed in such industries. In general, mechanized and automatic systems are expected to perform safely with designed performance most of the time or even round the clock. However, owing to design deficiencies or the influence of operational and environmental stresses, these systems are not completely failure free and are unable to meet customer requirements in terms of system performance. This is often attributed to poorly designed reliability and maintainability characteristics, combined with poor maintenance and product support strategies. If the designed reliability and maintainability characteristics are poor and the maintenance preparedness is unable to meet the users' requirements, this may result in a poor availability performance.

Reliability and maintainability are commonly regarded as engineering characteristics of the technical system, dimensioned during the design and development phase of the system's life cycle, whereas maintenance support is dependent on the users' organizational and operational effectiveness, including their operating environments. All these factors have an impact on the risks (or uncertainties) related to the availability performance of the system. A high availability performance level is an important and critical requirement for most of the technical systems. The factors influencing availability performance of engineering systems include reliability, maintainability, and maintenance support (see Figure 1). Even though high reliability is desirable to reduce the costs of maintenance and maintenance preparedness, the benefits of improved maintainability should not be overlooked in achieving the required availability performance. High maintainability performance results in high availability performance as the system is easy to maintain and repair.

Availability Concepts

Availability is generally the most appropriate measure for the performance of repairable items [1].

Availability performance is described by the collective term *dependability* and is a function of reliability performance, maintainability performance, and maintenance support performance as illustrated in Figure 1.

Availability Performance

The formal definition provided by the International Electrotechnical Vocabulary (IEV) (IEV 191-02-05) is as follows [2]: "The ability of an item to be in a state to perform a required function under given conditions at a given instant of time or over a given time interval, assuming that the required external resources are provided".

This means that availability is related to the state of an item (system, equipment, component, etc.), whether or not it is operating. The availability of safety or backup systems is quite an important matter of interest, highlighting the need for system and component state or health information.

Related to availability performance, there are various measures of availability, e.g., instantaneous and mean availability, respectively, and asymptotic availability measures. The most frequently used measure of availability is defined as the ratio between the time during which the equipment is available for use and the total planned time for operation: $availability = \frac{up-time}{total\ planned\ time}$.

A more abstract availability measure can be defined as follows: "the probability that a system will be in a functioning state on demand".

This definition is very important from a safety point of view. It is often used in defining the state and condition of the safety equipment, and is used frequently in the oil and gas industry and nuclear power plants. The safety equipment monitors the plant and processes for any unsafe state. Upon the detection of an unsafe state, the safety equipment acts or initiates actions to prevent a hazardous situation from developing. When the safety equipment is in a nonoperational state when required to function, then it is termed *unavailable*. As the arrival of an unsafe state occurs at random, it is desirable that the safety equipment should be available all the time, i.e., it is desirable to have a high level of availability. For highly dependable systems it is often more appropriate to focus on unavailability rather than on availability [3]. The measures are closely related: $unavailability = 1 - availability$ e.g., the

Figure 1 Dependability and availability concepts

effect of reducing the unavailability by 50%, from 0.0024 to 0.0012, is easier to comprehend than the effect of increasing the availability by 0.12%, from 0.9976 to 0.9988.

Similarly, this definition is useful to define the performance of the standby systems. In a production system with a standby production line, it is desirable that the standby system should start on demand. Such a demand is generated by the failure of the primary system or component.

For a continuously operating system, it is natural to define availability as “the probability that the system or a component is working at a specified time t ”. Upon the occurrence of failure, a repair process is initiated to bring the system back into the functioning state.

Many times, availability is also defined depending on whether the waiting time or the preventive maintenance times are included in or excluded from the calculation of the availability of the system. Inherent availability, achieved availability, and operational availability are some of the important measures used to quantify the extent to which an item is in an operational state, depending on whether the preventive maintenance time and the waiting time, apart from the active repair time, are taken into consideration. These categories of availability are defined as follows [4]:

1. Inherent availability (A_i)

The inherent availability is “the probability that a system or equipment, when used under stated conditions in an ideal support environment (e.g., readily available tools, spares, maintenance personnel, etc.), will operate satisfactorily at any point in time as required”. It excludes preventive or scheduled maintenance actions and logistics delay time, and is expressed as

$$A_i = \frac{MTBF}{MTBF + MTTR} \quad (1)$$

where $MTBF$ is the mean time between failure (*see Reliability Growth Testing; Reliability Data*) and $MTTR$ is the mean time to repair (*see Systems Reliability; Markov Modeling in Reliability*).

A_i is used for evaluation of different design alternatives to meet the design specification from system users.

2. Achieved availability (A_a)

Achieved availability is defined in a similar way as A_i – except that preventive (e.g., scheduled) maintenance is included. It excludes logistics delay time and administrative delay time and is expressed as

$$A_a = \frac{MTBM}{MTBM + \bar{M}} \quad (2)$$

where $MTBM$ is the mean time between maintenance and $\bar{M}$ the mean active maintenance time. $MTBM$ is a function of maintenance actions while $\bar{M}$ is a function of repair and service times.

A_a is used to assess the suitability of various preventive maintenance programs so as to meet the design specification from customers.

3. Operational availability (A_o)

Operational availability is “the probability that a system or an item of equipment, when used under stated conditions in an actual operational environment, will operate satisfactorily when called upon”. It is expressed as

$$A_o = \frac{MTBM}{MTBM + MDT} \quad (3)$$

where MDT is the mean maintenance downtime. The reciprocal of $MTBM$ is the frequency of maintenance, which in turn is a significant factor in determining logistic support requirements. MDT includes active maintenance time, logistics delay time, and administrative delay time.

A_o is used during the system operation phase to assess its performance in real situation.

Table 1 summarizes the various availability measures discussed earlier.

The term *availability* is used differently in different situations. If one is to improve an availability figure of merit as a design requirement for a given equipment design, and the designer has no control over the operational environment in which that equipment is to function, then A_a or A_i might be an

Table 1 Various availability measures

Concept	Calculation formula	Times included in calculations			Application area
		Reactive maintenance	Preventive and scheduled maintenance	Logistic and administrative delay	
General	$A = \frac{Up = time}{Total\ planned\ time}$	✓	✓	✓	Production
Inherent availability	$A_i = \frac{MTBF}{MTBF + MTTR}$	✓	–	–	System design
Achieved availability	$A_a = \frac{MTBM}{MTBM + \bar{M}}$	✓	✓	–	System design and maintenance planning
Operational availability	$A_o = \frac{MTBM}{MTBM + MDT}$	✓	✓	✓	Operation

appropriate figure of merit according to which equipment can be properly assessed. Conversely, if one is to assess a system in a realistic operational environment, then A_o is a preferred figure of merit to use for assessment purposes.

Furthermore, availability is defined differently by different groups depending on their background and interest. Many times there is no agreement on the meaning of downtime in the same organization, leading to different values of availability calculated for the same plant in the same period. Often, it is difficult to agree on what downtime is, as downtime to one person may not be downtime to another. To some people, downtime is related exclusively to machine health and does not include factors such as the waiting time for repair when a repairman is not available or the waiting time due to nonavailability of spare parts. There is no universally accepted definition of availability.

Example 1 Load haul dump (LHD) machines are used in many underground mines for loading and transportation of ore and other minerals.

The following data are extracted from the operation and maintenance card of an LHD machine deployed in a Swedish mine for the month of March, 2007. The machine was scheduled for 16h of operation per day for 23 days i.e., machine was scheduled for 368h of operation during the month; and no preventive maintenance actions were planned or performed.

All times are in hours.

Times between failure (TBF): 110.0, 13.0, 72.0, 4.0, 45.0, 56.0, 19.0.

Times to repair (TTR) including logistics and administrative delays: 7.5, 9.0, 6.3, 1.2, 2.6, 21.1, 1.3.

Active repair times (without logistics and administrative delays): 4.0, 6.5, 5.6, 1.0, 2.4, 11.0, 1.0.

In this case, A_i and A_a will be the same since no preventive maintenance action is performed.

To calculate A_a , we need to consider only the TBF (mean active operation time) and mean active repair time.

MTBM

= Mean times between failures(or maintenance)

$$= \frac{\text{Arithmetic sum of the TBF}}{\text{number of failures}}$$

$$= 319/7 = 45.6 \quad (4)$$

MDT

$$= \frac{\text{Arithmetic sum of the downtimes}}{\text{number of repairs}}$$

$$= 49/7 = 7 \quad (5)$$

Mean active repair time :

$$= \frac{\text{arithmetic sum of the active repair time}}{\text{number of repairs performed}}$$

$$= 31.5/7 = 4.5 \quad (6)$$

Achieved availability = A_a

$$= \frac{MTBM}{MTBM + \overline{M}} = 45.6/(45.6 + 4.5) = 91.1 \quad (7)$$

Operational availability = A_o

$$= \frac{MTBM}{MTBM + MDT} = 45.6/(45.6 + 7) = 86.7 \quad (8)$$

In an organization with world class logistics, i.e., without any logistics or administrative delays, the value of A_o should be approaching A_a .

Example 2 In the same mine, a detailed examination of the drill performance report showed two different figures for the availability of the heavy duty drill machines. One figure ($A_o = 81.5\%$) was reported by the production department and other figure ($A_o = 85\%$) by the contractor responsible for repair and maintenance of drill machines. The contract also has a provision for rewarding the contractor if he delivers better than minimum agreed availability target of 85% and penalizing the contractor if he fails to meet the minimum availability target of 85%.

A close study of all the facts and available records showed that the discrepancies in reporting availability figures were mainly owing to the fact that the maintenance contractor had not treated the high noise level in drill machine as a failure mode because the machine was functionally *ready* for operation. However, the operator refused to operate the machine saying that the high level of noise makes the machine unsuitable for operation, and declaring it *not ready* for operation.

Therefore, many times it is difficult to agree on the definition of machine breakdown, leading to different availability values of the same machine during the same period being provided by different parties.

From the above examples, we see that the availability performance of an engineering system is dependent on reliability performance, maintainability performance, and maintenance support performance.

Reliability Performance

Decisions regarding the reliability characteristics of an item of equipment are taken during the drawing board stage of equipment development. The aim is to prevent the occurrence of failures and also to eliminate their effects on the operational capability of the systems. The factors that have an important influence on the equipment reliability are

- period of use
- environment of use.

The formal definition of reliability according to IEV (191-02-06) is as follows [2]: “The ability of an item to perform required function under given conditions for a given time interval”.

A keyword is “a required function”. This means that it is possible to consider a number of “reliabilities” for a certain item, taking into account one requirement at a time. Of special interest are the safety functions or barriers related to the item under study. Another important word combination is “under given conditions”. It is essential that all the different foreseeable uses (and misuses) of the system under study should be considered when the requirements are identified. During the design of a system or item of equipment, the aim is to prevent the occurrence of failures as far as possible and also to reduce the effects of the failures that cannot be eliminated. The reliability of a system in operation is not determined solely by inherent design properties. A number of other factors such as operating environment, quality of repair and maintenance works performed, and so on, are taken into consideration.

Even though the system may have good reliability characteristics, the performance of the system may be poor because of scant attention paid to maintainability characteristics during the design phase.

Maintainability Performance

Maintainability is a design characteristic governed by design specification and is decided during the design and development phase of systems. It has a direct impact on availability in the sense that the time taken to locate faults and carry out routine preventive maintenance tasks contributes to the system downtime [4, 5]. Maintainability (*see Reliability Integrated Engineering Using Physics of Failure; No Fault Found*) and maintenance (*see Evaluation of Risk Communication Efforts; Repair, Inspection, and Replacement Models*) have always been important to the industry as they affect the system performance and thereby have a direct impact on the financial result of a company.

The objective of the maintainability input is to minimize the maintenance times and labor hours while maximizing the supportability characteristics in design (e.g., accessibility, diagnostic provisions, standardization, interchangeability), minimize the logistic

support resources required in the performance of maintenance (e.g., spare parts and supporting inventories, test equipment, maintenance personnel), and also minimize the maintenance cost.

The formal definition of maintainability is as follows (IEV 191-02-07) [2]: “The ability of an item under given conditions of use, to be retained in, or restored to, a state in which it can perform a required function, when maintenance is performed under given conditions and using stated procedures and resources”.

It is important to note that the ability to be retained in a satisfactory state is included, and not just the ability to be restored to a satisfactory state. Also note the important words *given conditions*. Often systems are designed, built, and tested in an environment with a comfortable temperature and good lighting. However, in real life, maintenance is often performed in a hostile environment, e.g., subarctic conditions or in tropical environments. The operating situation needs to be taken into account when designing for good maintainability. Robinson *et al.* [6] present an interesting discussion on the field maintenance interface between human engineering and maintainability engineering.

High maintainability performance and, in turn, high availability performance are obtained when the system is easy to maintain and repair. In general, the maintainability is measured by the mean repair time, often called *mean time to repair*, which includes the total time for fault finding, and the actual time spent in carrying out the repair. Both the way in which a system is designed and its installation have a direct bearing on the maintainability of the system. For capital-intensive equipment, the maintainability parameter influences the cost of life cycle more intensively than in the case of smaller equipment or throwaway consumer goods. Maintainability considerations are also very important for units operating under tough conditions, for instance, mining equipment. There exist numerous guidelines for taking maintainability into account [4, 7–10]. These guidelines are also very useful in the analysis of maintainability-related risks. The various aspects of maintainability may be grouped as shown in Figure 2.

Maintainability, as mentioned earlier, measures the ease and speed with which a system can be restored to an operational status after a failure occurs. Measures of maintainability are normally related to

the distribution of time needed for the performance of specified maintenance actions. For example, if it is said that a particular component has 90% maintainability in 1 h, this means that there is a 90% probability that the component will be repaired within an hour. Furthermore, there always exist risks associated with the performance of the organization that can be controlled and minimized by improving the maintainability of the system.

Sometimes the term *maintainability* is confused with maintenance. Maintainability is the ability of a product to be maintained, whereas maintenance constitutes a series of actions to be taken to restore a product to or retain it in an effective operational state. Maintainability is a design-dependent parameter. Maintenance is a result of design and operating environment. Ergonomic considerations in design for maintainability and also in the design of maintenance facilities have an important influence on the repair time and thereby on the availability of the system.

Various attempts have been made by researchers to develop procedures for evaluation of the maintainability of the various systems [11, 12].

Maintenance Support Performance

This final subconcept of availability is defined as follows (IEV 191-02-08) [2]: “The ability of a maintenance organization, under given conditions to provide upon demand the resources required to maintain an item, under a given maintenance policy”.

Thus, we can see that maintenance support performance is part of the wider concept of “product support”, including support to the product as well as support to the client.

Maintenance support is developed and maintained within the framework of corporate objectives. Defining and developing maintenance procedures, procurement of maintenance tools and facilities, logistic administration, documentation, and development and training programs for maintenance personnel are some of the essential features of a maintenance support system (Figure 3).

Availability, Maintainability, and Risk

The main factors to be considered when dealing with risks are the risk sources, or hazards, and the objects of harm. A risk source, or hazard, is defined as an

Figure 2 A number of factors influencing maintainability

Figure 3 Some aspects of maintenance support

item or activity having a potential for an undesired consequence [13], and an object of harm is defined as any object, within the delimitations of the analysis, that can suffer a loss of some kind owing to the impact of a risk source. The risk sources related to availability and maintainability are of several types, mostly connected to the planning and performance of maintenance. The list of maintenance aspects is very helpful in this respect. The objects of harm range from the system under study, in its business and physical environment, down to components subject to repair or replacement.

The description of the risks identified can be made using scenarios starting with an initiating event from a risk source and ending with possible consequences for different objects of harm. The various mind maps, describing the factors influencing the reliability performance, maintainability performance, and maintenance support performance, respectively, may be used as checklists in the identification of risk sources. Experience from maintenance work within different fields may be used for the more concrete description of the risk sources. Some examples are as follows:

- Poor accessibility may lead to the use of inappropriate access paths, jeopardizing adjacent equipment, and components.
- Poor exchangeability, in the sense that physically exchangeable parts may have different performance characteristics, may lead to serious malfunctions.

- Disassembly difficulties may lead to the use of extra high forces, causing damage, e.g., to structure components.

Conclusions

Availability is the most commonly used measure of the state of plant and systems all over the world, and maintainability performance is the universal measure of the maintenance friendliness of systems. Not only are the availability and maintainability measures of system performance, but they also have considerable influence on the financial performance and survival of businesses. Designing and using systems that are maintenance friendly significantly improves the safety and also system availability performance. It is true that improved reliability is the best route to achieve higher availability performance; the benefits of improved maintainability should not be ignored. Many times, it is easier and cost effective to meet the availability performance requirement through improvement in maintainability characteristics than through improvement in reliability characteristics of the system.

Axiomatic Measures of Risk and Risk-Value Models

This article provides a review of measures of risk and risk-value models that have been developed over the past 10 years to provide a new class of decision making models based on the idea of risk-value trade-offs. The measurement of risk has been a critical issue in decision sciences, finance, and other fields for many years (*see* **Decision Modeling; Model Risk; Simulation in Risk Management; Environmental Health Risk**). We focus on a preference-dependent measure of risk that can be used to derive risk-value models within both an expected utility framework and a nonexpected utility framework. Although this measure of risk has some descriptive power for risk judgments, it is more normative in nature. We treat the issue of measures of perceived risk in a separate article (*see* **Axiomatic Models of Perceived Risk**).

Intuitively, individuals may consider their choices over risky alternatives by trading off between risk and return, where return is typically measured as the mean (or expected return) and risk is measured by some indicator of dispersion or possible losses. Markowitz [1–3] proposed variance as a measure of risk, and a mean–variance model for portfolio selection based on minimizing variance subject to a given level of mean return. Arguments have been put forth that mean–variance models are appropriate only if the investor’s utility function is quadratic or the joint distribution of returns is normal. However, these conditions are rarely satisfied in practice. Markowitz also suggested semivariance as an alternative measure of risk. Some other measures of risk, such as lower partial moment risk measures and absolute standard deviation, have also been proposed in the financial literature (e.g. [4]). However, without a common framework for risk models, it is difficult to justify and evaluate these different measures of risk as components of a decision making process.

Expected utility theory is generally regarded as the foundation of mean-risk models and risk-return models (e.g. [5–9]). However, expected utility theory has been called into question by empirical studies of risky choice (e.g. [10–14]). This suggests that an

alternative approach regarding the paradigm of risk-return trade-offs would be useful for predicting and describing observed preferences.

In the mainstream of decision research (*see* **Decision Modeling**), the role of risk in determining preference is usually considered implicitly. For instance, in the expected utility model [15], an individual’s attitude toward the risk involved in making choices among risky alternatives is defined by the shape of his or her utility function [16, 17]; and in some non-expected utility models, risk (or “additional” risk) is also captured by some nonlinear function over probabilities (e.g. *see* [12, 18–20]). Thus, these decision theories are not, at least explicitly, compatible with the choice behavior based on the intuitive idea of risk-return trade-offs as often observed in practice. Therefore, they offer little guidance for this type of decision making.

In this article, we review our risk-value studies and provide an axiomatic measure of risk that is compatible with choice behavior based on risk-value trade-offs. In particular, this framework unifies two streams of research: one in modeling risk judgments and the other in developing preference models. This synthesis provides risk-value models that are more descriptively powerful than other preference models and risk models that have been developed separately.

The remainder of this article is organized as follows. The next section describes a preference-dependent measure of risk with several useful examples. The section titled “Frameworks for Risk-Value Trade-off” reviews the basic framework of our risk-value studies and related preference conditions. The section titled “Generalized Risk-Value Models” presents three specific forms of risk-value models. The last section summarizes the applicability risk-value studies and discusses topics for future research.

The Standard Measure of Risk

As a first step in developing risk-value models, Jia and Dyer [21] propose a preference-dependent measure of risk, called a *standard measure of risk*. This general measure of risk is based on the converse expected utility of normalized lotteries with zero-expected values, so it is compatible with the measure of expected utility and provides the basis for linking risk with preference.

For lotteries with zero-expected values, we assume that the only choice attribute of relevance is risk. A riskier lottery would be less preferable and vice versa, for any risk averse decision maker. Therefore, the riskiness ordering of these lotteries should be simply the reverse of the preference ordering. However, if a lottery has a nonzero mean, then we assume that the risk of that lottery should be evaluated relative to a “target” or reference level. The expected value of the lottery is a natural reference point for measuring the risk of a lottery.

Therefore, we consider decomposing a X (i.e., a random variable) into its mean $\bar{X}$ and its standard risk, $X' = X - \bar{X}$, and the standard measure of risk is defined as follows:

$$R(X') = -E[u(X')] = -E[u(X - \bar{X})] \quad (1)$$

where $u(\cdot)$ is a utility function [15] and the symbol E represents expectation over the probability distribution of a lottery.

One of the characteristics of this standard measure of risk is that it depends on an individual's utility function. Once the form of the utility function is determined, we can derive the associated standard measure of risk over lotteries with zero means. More important, this standard measure of risk can offer a preference justification for some commonly used measures of risk, so that the suitability of those risk measures can be evaluated.

If a utility function is quadratic, $u(x) = ax - bx^2$, where $a, b > 0$, then the standard measure of risk is characterized by variance, $R(X') = bE[(X - \bar{X})^2]$. However, the quadratic utility function has a disturbing property; that is, it is decreasing in x after a certain point, and it exhibits increasing risk aversion. Since the quadratic utility function may not be an appropriate description of preference, it follows that variance may not be a good measure for risk (unless the distribution of a lottery is normal).

To obtain a related, but increasing, utility function, consider a third-order polynomial (or cubic) utility model, $u(x) = ax - bx^2 + c'x^3$, where $a, b, c' > 0$. When $b^2 < 3ac'$, the cubic utility model is increasing. This utility function is concave, and hence risk averse for low outcome levels (i.e., for $x < b/(3c')$), and convex, and thus risk seeking for high outcome values (i.e., for $x > b/(3c')$). Such a utility function may be used to model a preference structure consistent with the observation that a large number of individuals purchase both insurance (a moderate outcome-small

probability event) and lottery tickets (a small chance of a large outcome) in the traditional expected utility framework [22]. The associated standard measure of risk for this utility function can be obtained as follows:

$$R(X') = E[(X - \bar{X})^2] - cE[(X - \bar{X})^3] \quad (2)$$

where $c = c'/b > 0$. Model (2) provides a simple way to combine skewness with variance into a measure of risk. This measure of risk should be superior to the one based on variance alone, since the utility function implied by equation (2) has a more intuitive appeal than the quadratic one implied by variance. Further, since equation (2) is not consistent with increasing risk aversion, for prescriptive purposes, it is more appropriate than variance.

Markowitz [23] noted that an individual with the utility function that is concave for low outcome levels and convex for high outcome values will tend to prefer positively skewed distributions (with large right tails) over negatively skewed ones (with large left tails). The standard measure of risk (equation (2)) clearly reflects this observation; i.e., a positive skewness will reduce risk and a negative skewness will increase risk.

If an individual's preference can be modeled by an exponential or a linear plus exponential utility function, $u(x) = ax - be^{-cx}$, where $a \geq 0$, and $b, c > 0$, then its corresponding standard measure of risk (with the normalization condition $R(0) = 1$) is given by

$$R(X') = E[e^{-c(X - \bar{X})} - 1] \quad (3)$$

Bell [7] identified $E[e^{-c(X - \bar{X})}]$ as a measure of risk from the linear plus exponential utility model by arguing that the riskiness of a lottery should be independent of its expected value. Weber [24] also modified Sarin's [25] expected exponential risk model by requiring that the risk measure be location free.

If an individual is risk averse for gains but risk seeking for losses as suggested by Prospect theory [12, 26], then we can consider a piecewise power utility model as follows:

$$u(x) = \begin{cases} ex^{\theta_1}, & \text{when } x \geq 0 \\ -d|x|^{\theta_2}, & \text{when } x < 0 \end{cases} \quad (4)$$

where e, d, θ_1 , and θ_2 are nonnegative constants. Applying equation (1), the corresponding standard

measure of risk is given by

$$R(X') = dE^-[|X - \bar{X}|^{\theta_2}] - eE^+[|X - \bar{X}|^{\theta_1}] \quad (5)$$

where $E^-[|X - \bar{X}|^{\theta_2}] = \int_{-\infty}^{\bar{X}} |x - \bar{X}|^{\theta_2} f(x) dx$, $E^+[|X - \bar{X}|^{\theta_1}] = \int_{\bar{X}}^{\infty} (x - \bar{X})^{\theta_1} f(x) dx$, and $f(x)$ is the probability density of a lottery.

The standard measure of risk (equation (5)) includes several commonly used measures of risk as special cases in the financial literature. When $d > e > 0$, $\theta_1 = \theta_2 = \theta > 0$, and the distribution of a lottery is symmetric, we have $R(X') = (d - e)E[|X - \bar{X}|^\theta]$, which is associated with variance and absolute standard deviation if $\theta = 2$ and $\theta = 1$, respectively. This standard measure of risk is also related to the difference between the parameters d and e that reflect the relative effect of loss and gain on risk. In general, if the distribution of a lottery is not symmetric, this standard measure of risk will not be consistent with the variance of the lottery even if $\theta_1 = \theta_2 = 2$, but it is still related to the absolute standard deviation if $\theta_1 = \theta_2 = 1$ [27].

Konno and Yamazaki [28] have argued that the absolute standard deviation is more appropriate for use in portfolio decision making than the variance, primarily due to its computational advantages. Dennenberg [29] argues that the average absolute deviation is a better statistic for determining the safety loading (premium minus the expected value) for insurance premiums than the standard deviation. These arguments suggest that in some applied contexts, the absolute standard deviation may be a more suitable measure of risk than variance.

Another extreme case of equation (5) arises when $e = 0$ (i.e., the utility function is nonincreasing for gains); then the standard measure of risk is a lower partial moment risk model $R(X') = dE^-[|X - \bar{X}|^{\theta_2}]$. When $\theta_2 = 2$, it becomes a semivariance measure of risk [1]; and when $\theta_2 = 0$, it reduces to the probability of loss.

To summarize, there are other proposed measures of risk that are special cases of this standard measure of risk. The standard measure of risk is more normative in nature, as it is independent of the expected value of a lottery. To obtain more descriptive power and to capture perceptions of risk, we have also established measures of perceived risk that are based on a two-attribute structure: the mean of a lottery and its standard risk [30], as described in a separate article in this encyclopedia (see **Axiomatic Models of Perceived Risk**).

Frameworks for Risk-Value Trade-off

When we decompose a lottery into its mean and standard risk, then the evaluation of the lottery can be based on the trade-off between mean and risk. We assume a risk-value preference function $f(\bar{X}, R(X'))$, where f is increasing in $\bar{X}$ and decreasing in $R(X')$ if one is risk averse.

Consider an investor who wants to maximize his or her preference function f for an investment and also requires a certain level μ of expected return. Since f is decreasing in $R(X')$ and $\bar{X} = \mu$ is a constant, maximizing $f(\bar{X}, R(X'))$ is equivalent to minimizing $R(X')$; i.e., $\max \{f(\bar{X}, R(X')) | \bar{X} = \mu\} \Rightarrow \min \{R(X') | \bar{X} = \mu\}$. This conditional optimization model includes many financial optimization models as special cases that depend on the choice of different standard measures of risk; e.g., Markowitz's mean-variance model, the mean-absolute standard deviation model, and the mean-semivariance model. Some new optimization models can also be formulated based on our standard measures of risk (equations (2) and (5)).

In the conditional optimization problem, we do not need to assume an explicit form for the preference function f . The problem only depends on the standard measure of risk. However, we may argue that an investor should maximize his or her preference functions unconditionally in order to obtain the overall optimal portfolio. For an unconditional optimization decision, the investor's preference function must be specified. Here, we consider two cases for the preference function f : (a) when it is consistent with the expected utility theory; and (b) when it is based on a two-attribute expected utility foundation.

Let $\mathbf{P}$ be a convex set of all simple probability or lotteries $\{X, Y, \dots\}$ on a nonempty set $\mathbf{X}$ of outcomes, and Re be the set of real numbers (assuming $\mathbf{X} \in \text{Re}$ is finite). We define $\succ$ as a binary preference relation on $\mathbf{P}$.

Definition 1 For two lotteries $X, Y \in \mathbf{P}$ with $E(X) = E(Y)$, if $w_0 + X \succ w_0 + Y$ for some $w_0 \in \text{Re}$, then $w + X \succ w + Y$, for all $w \in \text{Re}$.

This is called the *risk independence condition*. It means that for a pair of lotteries with a common mean, the preference order between the two lotteries will not change when the common mean changes; i.e., preference between the pair of lotteries can be

determined solely by the ranking of their standard risks.

Result 1 *Assume that the risk-value preference function f is consistent with expected utility theory. Then f can be represented as the following standard risk-value form,*

$$f(\bar{X}, R(X')) = u(\bar{X}) - \varphi(\bar{X})[R(X') - R(0)] \quad (6)$$

if and only if the risk independence condition holds, where $\varphi(\bar{X}) > 0$ and $u(\cdot)$ is a von Neumann and Morgenstern [15] utility function.

Model (6) shows that an expected utility model could have an alternative representation if this risk independence condition holds. If one is risk averse, then $u(\cdot)$ is a concave function, and $R(X') - R(0)$ is always positive. $u(\bar{X})$ provides a measure of value for the mean. If we did not consider the riskiness of a lottery X , it would have the value $u(\bar{X})$. Since it is risky, $u(\bar{X})$ is reduced by an amount proportional to the normalized risk measure $R(X') - R(0)$. $\varphi(\bar{X})$ is a trade-off factor that may depend on the mean. If we further require the utility model to be continuously differentiable, then it must be either a quadratic, exponential, or linear plus exponential model [21].

There are also some other alternative forms of risk-value models within the expected utility framework under different preference conditions [8, 9, 31]. In addition, for nonnegative lotteries such as those associated with the price of a stock, Dyer and Jia [32] propose a relative risk-value framework in the form $X = \bar{X} \times (X/\bar{X})$ that decomposes the return into an average return $\bar{X}$ and a percentage-based risk factor $X/\bar{X}$. We find that this form of a risk-value model is compatible with the logarithmic (or linear plus logarithmic) and the power (or linear plus power) utility functions [32]. Recent empirical studies by Weber *et al.* [33] indicate that this formulation may also be useful as the basis for a descriptive model of the sensitivity of humans and animals to risk.

However, the notion of risk-value trade-offs within the expected utility framework is very limited; for example, consistency with expected utility, based on model (6), imposes very restrictive conditions on the relationship between the risk measure $R(X') = -E[u(X - \bar{X})]$, the value measure $u(\bar{X})$, and the trade-off factor $\varphi(\bar{X}) = u''(\bar{X})/u''(0)$ (for continuously differentiable utility models). In particular, the risk measure and the value measure

must be based on the same utility function. However, a decision maker may deviate from this “consistency” and have different measures for risk and value if his choice is based on risk-value trade-offs.

To be more realistic and flexible in the framework of risk-value trade-offs, we consider a two-attribute structure $(\bar{X}, X')$ for the evaluation of a risky alternative X . In this way, we can explicitly base the evaluation of lotteries on two attributes, mean and risk, so that the mean-risk (or risk-value) trade-offs are not necessarily consistent with the traditional expected utility framework.

We assume the existence of the von Neumann and Morgenstern expected utility axioms over the two-attribute structure $(\bar{X}, X')$ and require the risk-value model to be consistent with the two-attribute expected utility model, i.e., $f(\bar{X}, R(X')) = E[U(\bar{X}, X')]$, where U is a two-attribute utility function. As a special case, when the relationship between $\bar{X}$ and X' is a simple addition, the risk-value model reduces to a traditional expected utility model, i.e., $f(\bar{X}, R(X')) = E[U(\bar{X}, X')] = E[U(\bar{X} + X')] = E[U(X)] = aE[u(X)] + b$, where $a > 0$ and b are constants.

To obtain some separable forms of the risk-value model, we need to have a risk independence condition for the two-attribute structure. Let P^0 be the set of normalized lotteries with zero-expected values, and $>$ a strict preference relation for the two-attribute structure.

Definition 2 For $X', Y' \in P^0$, if there exists a $w_0 \in \text{Re}$ for which $(w_0, X') > (w_0, Y')$, then $(w, X') > (w, Y')$, for all $w \in \text{Re}$.

This two-attribute risk independence condition requires that if two lotteries have the same mean and one is preferred to the other, then transforming the lotteries by adding the same constant to all outcomes will not reverse the preference ordering. This condition is generally supported by our recent experimental studies [34].

Result 2 *Assume that the risk-value preference function f is consistent with the two-attribute expected utility model. Then f can be represented as the following generalized risk-value form,*

$$f(\bar{X}, R(X')) = V(\bar{X}) - \phi(\bar{X})[R(X') - R(0)] \quad (7)$$

if and only if the two-attribute risk independence condition holds, where $\phi(\bar{X}) > 0$ and $R(X')$ is the standard measure of risk.

In contrast to the standard risk-value model (6), the generalized risk-value model (7) provides the flexibility of considering $V(\bar{X})$, $R(X')$ and $\phi(\bar{X})$ independently. Thus we can choose different functions for the value measure $V(\bar{X})$, independent of the utility function. The expected utility measure is used only for the standard measure of risk. Even though expected utility theory has been challenged by some empirical studies for general lotteries, we believe that it should be appropriate for describing risky choice behavior within a special set of normalized probability distributions with the same expected values. For general lotteries with different means, however, our two-attribute risk-value model can deviate from the traditional expected utility preference. In fact, the generalized risk-value model can capture a number of decision paradoxes that violate the traditional expected utility theory [35].

If the utility function u is strictly concave, then $R(X') - R(0) > 0$ and model (7) will reflect risk averse behavior. In addition, if $V(\bar{X})$ is increasing and twice continuously differentiable, $\phi(\bar{X})$ is once continuously differentiable, and $\phi'(\bar{X})/\phi(\bar{X})$ is nonincreasing, then the generalized risk-value model (7) exhibits decreasing risk aversion if and only if $-V''(\bar{X})/V'(\bar{X}) < -\phi'(\bar{X})/\phi(\bar{X})$; and the generalized risk-value model (7) exhibits constant risk aversion if and only if $-V''(\bar{X})/V'(\bar{X}) = -\phi'(\bar{X})/\phi(\bar{X})$ is a constant. Thus, if a decision maker is decreasingly risk averse and has a linear value function, then we must choose a decreasing function for the trade-off factor $\phi(\bar{X})$.

The basic form of the risk-value model may be further simplified if some stronger preference conditions are satisfied. When $\phi(\bar{X}) = k > 0$, model (7) becomes the following additive form:

$$f(\bar{X}, R(X')) = V(\bar{X}) - k[R(X') - R(0)] \quad (8)$$

When $\phi(\bar{X}) = -V(\bar{X}) > 0$, then model (7) reduces to the following multiplicative form:

$$f(\bar{X}, R(X')) = V(\bar{X})R(X') \quad (9)$$

where $R(0) = 1$ and $V(0) = 1$. In this multiplicative model, $R(X')$ serves as a value discount factor due to risk.

We describe measures of perceived risk based on the converse interpretation of the axioms of risk-value models in a companion article in this collection (see **Axiomatic Models of Perceived Risk**). These perceived risk models are simply a negative linear transformation of the risk-value model (7) [30]. Our risk-value framework offers a unified approach to both risk judgment and preference modeling.

Generalized Risk-Value Models

According to the generalized risk-value model (7), the standard measure of risk, the value function, and the trade-off factor can be considered independently. Some examples of the standard measure of risk $R(X')$ are provided in the section titled “The Standard Measure of Risk”. The value measure $V(\bar{X})$ should be chosen as an increasing function and may have the same functional form as a utility model. For appropriate risk averse behavior, the trade-off factor $\phi(\bar{X})$ should be either a decreasing function or a positive constant; e.g., $\phi(\bar{X}) = ke^{-b(\bar{X})}$, where $k > 0$ and $b \geq 0$. We consider three types of risk-value models, namely, moments risk-value models, exponential risk-value models, and generalized disappointment models as follows. For the corresponding perceived risk of each risk-value model (see **Axiomatic Models of Perceived Risk**).

Moments Risk-Value Models

People often use mean and variance to make trade-offs for financial decision making because they provide a reasonable approximation for modeling decision problems and are easy to implement (see [1–3, 36, 37]). In the past, expected utility theory has been used as a foundation for mean–variance models. Risk-value theory provides a better foundation for developing moments models that include the mean–variance model as a special case.

As an example, the mean–variance model, $\bar{X} - kE[(X - \bar{X})^2]$, where $k > 0$, is a simple risk-value model with variance as the standard measure of risk and a constant trade-off factor. Sharpe [36, 37] assumed this mean–variance model in his analysis for portfolio selection and the capital asset pricing model. However, under the expected utility framework, this mean–variance model is based on the assumptions that the investor has an exponential utility function and that returns are jointly normally distributed.

According to our risk-value theory, this mean–variance model is constantly risk averse. To obtain a decreasing risk averse mean–variance model, we can simply use a decreasing function for the trade-off factor:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[(X - \bar{X})^2] \quad (10)$$

where $b, k > 0$.

For many decision problems, mean–variance models are an over simplification. On the basis of this risk-value framework, we can specify some richer moment models for risky decision making. First, let us consider the moment standard measure of risk (equation (2)) for the additive risk-value model (8):

$$f(\bar{X}, R(X')) = \bar{X} - k \{E[(X - \bar{X})^2] - cE[(X - \bar{X})^3]\} \quad (11)$$

where $c, k > 0$. The three moments model (11) can be either risk averse or risk seeking, depending on the distribution of a lottery. For symmetric bets or lotteries not highly skewed (e.g., an insurance policy) such that $E[(X - \bar{X})^2] > cE[(X - \bar{X})^3]$, model (11) will be risk averse. But for highly positive skewed lotteries (e.g., lottery tickets) such that the skewness overwhelms the variance, i.e., $E[(X - \bar{X})^2] < cE[(X - \bar{X})^3]$, then model (11) will exhibit risk seeking behavior. Therefore, an individual with preferences described by the moments model (11) would purchase both insurance and lottery tickets simultaneously.

Markowitz [23] noticed that individuals have the same tendency to purchase insurance and lottery tickets whether they are poor or rich. This observed behavior contradicts a common assumption of expected utility theory that preference ranking is defined over ultimate levels of wealth. But whether our risk-value model is risk averse or risk seeking is determined only by the standard measure of risk, which is independent of an individual's wealth level (refer to the form of risk-value model (4)). In particular, for the three moments model (10), the change of wealth level only causes a parallel shift for $f(\bar{X}, R(X'))$ that will not affect the risk attitude and the choice behavior of this model. This is consistent with Markowitz's observation.

Exponential Risk-Value Models

If the standard measure of risk is based on exponential or linear plus exponential utility models, then the

standard measure of risk is given by equation (3). To be compatible with the form of the standard measure of risk, we can also use exponential functions, but with different parameters, for the value measure $V(\bar{X})$ and the trade-off factor $\phi(\bar{X})$, for the generalized risk-value model (7) which then leads to the following model:

$$f(\bar{X}, R(X')) = -he^{-a\bar{X}} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1] \quad (12)$$

where a, b, c, h , and k are positive constants. When $a = b = c$ and $h = k$, this model reduces to an exponential utility model; otherwise, these two models are different. When $b > a$, model (12) is decreasing risk averse even though the traditional exponential utility model exhibits constant risk aversion.

As a special case, when $a = b$ and $h = k$, model (12) reduces to the following simple multiplicative form:

$$f(\bar{X}, R(X')) = ke^{-a\bar{X}}E[e^{-c(X-\bar{X})}] \quad (13)$$

This model is constantly risk averse, and therefore has the same risk attitude as an exponential utility model. It has more flexibility since there are two different parameters. This simple risk-value model can be used to explain some well known decision paradoxes [35].

Choosing a linear function or a linear plus exponential function for $V(\bar{X})$ leads to the following models:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1] \quad (14)$$

$$f(\bar{X}, R(X')) = \bar{X} - he^{-a\bar{X}} - ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1] \quad (15)$$

Model (14) is decreasingly risk averse. Model (15) includes a linear plus exponential utility model as a special case when $a = b = c$ and $h = k$. It is decreasingly risk averse if $b \geq a$.

Generalized Disappointment Models

Bell [38] proposed a disappointment model for decision making under uncertainty. According to Bell, disappointment is a psychological reaction to an outcome that does not meet a decision maker's expectation. Bell used the mean of a lottery as a decision

maker's psychological expectation. If an outcome smaller than the expected value occurs, the decision maker would be disappointed. Otherwise, the decision maker would be elated. Although Bell's development of the disappointment model has an intuitive appeal, his model is only applicable to lotteries with two outcomes.

Jia *et al.* [27] use the risk-value framework to develop a generalized version of Bell's [38] disappointment model. Consider the following piecewise linear utility model:

$$u(x) = \begin{cases} ex & \text{when } x \geq 0 \\ dx & \text{when } x < 0 \end{cases} \quad (16)$$

where $d, e > 0$ are constant. Decision makers who are averse to downside risk or losses should have $d > e$, as illustrated in Figure 1. The standard measure of risk for this utility model can be obtained as follows:

$$\begin{aligned} R(X') &= dE^- [|X - \bar{X}|] - eE^+ [|X - \bar{X}|] \\ &= [(d - e)/2]E[|X - \bar{X}|] \end{aligned} \quad (17)$$

where $E^- [|X - \bar{X}|] = \sum_{x_i < \bar{X}} p_i |x_i - \bar{X}|$ and $E^+ [|X - \bar{X}|] = \sum_{x_i > \bar{X}} p_i (x_i - \bar{X})$, and $E[|X - \bar{X}|]$ is the absolute standard deviation. Following Bell's [38] basic idea, $dE^- [|X - \bar{X}|]$ represents a general measure of expected disappointment and $eE^+ [|X - \bar{X}|]$ represents a general measure of expected elation. The overall psychological satisfaction is measured by $-R(X')$, which is the converse of the standard measure of risk (equation (17)).

Figure 1 A piecewise linear utility function

If we assume a linear value measure and a constant trade-off factor, then we can have the following risk-value model based on the measure of disappointment risk (equation (17)):

$$\begin{aligned} f(\bar{X}, R(X')) &= \bar{X} - \{dE^- [|X - \bar{X}|] - eE^+ [|X - \bar{X}|]\} \\ &= \bar{X} - [(d - e)/2]E[|X - \bar{X}|] \end{aligned} \quad (18)$$

For a two-outcome lottery, model (18) reduces to Bell's disappointment model. Thus, we call the risk-value model (18) a "generalized disappointment model". Note that the risk-value model (18) will be consistent with the piecewise linear utility model (16) when the lotteries considered have the same means. It is a risk averse model when $d > e$.

Using his two-outcome disappointment model, Bell gave an explanation for the common ratio effect [38]. Our generalized disappointment model (18) can explain the Allais Paradox [10, 11], which involves an alternative with three outcomes [27]. Bell's model and (18) both imply constant risk aversion and are not appropriate for decreasingly risk averse behavior. To obtain a disappointment model with decreasing risk aversion, we can use a decreasing function for the trade-off factor:

$$f(\bar{X}, R(X')) = \bar{X} - ke^{-b\bar{X}}E[|X - \bar{X}|] \quad (19)$$

Bell's disappointment model (18) implies that disappointment and elation are proportional to the difference between the expected value and an outcome. We can use risk model (5) to incorporate nonlinear functions for disappointment and elation in a more general form of disappointment model:

$$\begin{aligned} f(\bar{X}, R(X')) &= \bar{X} - dE^- [|X - \bar{X}|^{\theta_2}] \\ &\quad - eE^+ [|X - \bar{X}|^{\theta_1}] \end{aligned} \quad (20)$$

When $\theta_1 = \theta_2 = 1$, this model reduces to model (18). When $e = 0$ and $\theta_2 = 2$, model (20) becomes a mean-semivariance model.

Finally, our generalized disappointment models are different from Loomes and Sugden's development [39]. In their basic model, disappointment (or elation) is measured by some function of the difference between the utility of outcomes and the expected utility of a lottery. They also assume a linear "utility" measure of wealth and the same sensation intensity for both disappointment and elation, so that

their model has the form, $\bar{X} + E[D(X - \bar{X})]$, where $D(x - \bar{X}) = -D(\bar{X} - x)$, and D is continuously differentiable and convex for $x > \bar{X}$ (thus concave for $x < \bar{X}$). Even though this model is different from our generalized disappointment models (20), it is a special case of our risk-value model with a linear measure of value, a constant trade-off factor, and a specific form of the standard measure of risk (i.e., $R(X') = -E[D(X - \bar{X})]$, where $D(x - \bar{X}) = -D(\bar{X} - x)$). Loomes and Sugden used this model to provide an explanation for the choice behavior that violates Savage's sure-thing principle [40].

Conclusion

We have summarized our efforts to incorporate the intuitively appealing idea of risk-value trade-offs into decision making under risk. The risk-value framework ties together two streams of research: one in modeling risk judgments and the other in developing preference models, and unifies a wide range of decision phenomena including both normative and descriptive aspects.

This development also refines and generalizes a substantial number of previously proposed decision theories and models, ranging from the mean-variance model in finance to the disappointment models in decision sciences. It is also possible to create many new risk-value models. Specifically, we have discussed three classes of decision models based on this risk-value theory: moments risk-value models, exponential risk-value models and generalized disappointment risk-value models. These models are very flexible in modeling preferences. They also provide new resolutions for observed risky choice behavior and the decision paradoxes that violate the independence axiom of the expected utility theory.

The most important assumption in this study is the two-attribute risk independence condition that leads to a separable form of risk-value models. Although some other weaker condition could be used to derive a risk-value model that has more descriptive power, this reduces the elegance of the basic risk-value form, and increases operational difficulty. Butler *et al.* [34] conducted an empirical study of this key assumption, and found some support for it. This study also highlighted some additional patterns of choices indicating that the translation of lottery pairs from the positive domain to the negative domain

often results in the reversal of preference and risk judgments. To capture this phenomenon, we have extended risk independence conditions to allow the trade-off factor in the risk-value models to change sign, and therefore to infer risk aversion in the positive domain and risk seeking in the negative domain. These generalized risk-value models provide additional insights into the reflection effects [12] and related empirical results [14, 26, 41].

Even though some other nonexpected utility theories that have been proposed (e.g., Prospect theory and other weighted utility theories) may produce the same predictions for the decision paradoxes as risk-value theory, it offers a new justification for them based on the appealing and realistic notion of risk-value trade-offs. In particular, since the role of risk is considered *implicitly* in these decision theories and models, they are not compatible with choice behavior that is based on the risk and mean return trade-offs often encountered in financial management, psychology, and other applied fields. Therefore, these theories and models offer little guidance in practice for this type of decision making. We believe that the potential for contributions of these risk-value models in finance is very exciting. Applications of our risk-value models in other fields such as economics, marketing, insurance and risk management are also promising.

Axiomatic Models of Perceived Risk

In a separate article in this encyclopedia (*see* **Axiomatic Measures of Risk and Risk-Value Models**), we discussed a standard measure of risk based on the converse of the expected utility of lotteries with zero-expected values, and showed how it could be used to derive risk-value models for risky choices within both an expected utility framework and a non-expected utility framework (see also [1–3]). Though this standard measure of risk has some descriptive power for risk judgments, it is more normative in nature. In particular, since the standard measure of risk eliminates the effect of the mean of a lottery, it only measures the “pure” risk of the lottery, and may not be appropriate for modeling perceptions of risk. The purpose of this article is to describe a two-attribute structure of perceived risk that allows the mean to impact judgments of risk perception and that can also be related to risk-value models for risky choice.

Over the last 30 years, researchers have expended much effort toward developing and testing models of the perceived riskiness of lotteries. Pollatsek and Tversky [4] provide an early summary of risk research that is still meaningful today:

The various approaches to study of risk share three basic assumptions. 1. Risk is regarded as a property of options (e.g., gambles, courses of action) that affects choices among them. 2. Options can be meaningfully ordered with respect to their riskiness. 3. The risk of an option is related in some way to the dispersion, or the variance, of its outcomes.

As stated in assumption 1, risk is a characteristic of a lottery that affects decisions. This is the primary motivation for studying the nature of perceived risk. A measure of perceived risk may be used as a variable in preference models, such as Coombs’ portfolio theory [5–8], in which a choice among lotteries is a compromise between maximizing expected value and optimizing the level of perceived risk. However, the “risk” measure in Coombs’ Portfolio theory is left essentially undefined, and is considered to be an independent theory. This has stimulated a long stream of research on the measure of perceived risk.

Empirical studies have demonstrated that people are consistently able to order lotteries with respect to

their riskiness, and that risk judgments satisfy some basic axioms (e.g., see [9, 10]). Thus, as stated in assumption 2, the term *riskiness* should be both a meaningful and measurable characteristic of lotteries.

There have been many refinements to assumption 3 as experimental results have exposed how perceived-risk judgments change as a function of the characteristics of the lotteries considered. Some stylized facts regarding risk judgments include the following:

- Perceived risk increases when there is an increase in range, variance, or expected loss, e.g., see [11].
- Perceived risk decreases if a constant positive amount is added to all outcomes of a lottery [9, 12].
- Perceived risk increases if all outcomes of a lottery with zero mean are multiplied by a positive constant greater than one [6].
- Perceived risk increases if a lottery with zero-mean is repeated many times [6].

These empirically verified properties provide basic guidelines for developing and evaluating measures of perceived risk.

In the following section, we give a review of previously proposed models of perceived risk and discuss their performance in empirical studies. In the section titled “Two-Attribute Models for Perceived Risk”, we present our measures of perceived risk based on a two-dimensional structure of the standard risk of a lottery and its mean, and show that it includes many of these previously proposed models as special cases. Finally, in the concluding section, we provide a summary and discuss the implications of the two-attribute perceived-risk structure in decision making under risk.

Review of Perceived Risk Models

The literature contains various attempts to define risk based on different assumptions about how perceived risk is formulated and how it evolves as the risky prospects under consideration are manipulated. In this section, we review some previously proposed models for perceived risk and their key assumptions. We focus on those that are closely related to a preference-dependent measure of risk that is compatible with traditional expected utility theory.

A more detailed review of perceived-risk studies, including some measures of risk that are not closely related to preference, is provided by Brachinger and Weber [13]. We also exclude from our discussion the “coherent measures of risk” developed in the financial mathematics literature by Artzner *et al.* [14, 15] which produce results in monetary units (for example, in dollars) that estimate the “expected shortfall” associated with a portfolio. For a recent review of the latter, see Acerbi [16].

Studies by Coombs and His Associates

In early studies, risk judgments were represented by using the moments of a distribution and their transformations, i.e., distributive models. Expected value, variance, skewness, range, and the number of repeated plays have been investigated as possible determinants of risk judgments [6, 11, 17]. Coombs and Huang [7] considered several composition functions of three indices corresponding to transformations on two-outcome lotteries, and their paper supported a distributive model that is based on a particular structure of the joint effect of these transformations on perceived risk. However, evidence to the contrary of such a distributive model was also found by Barron [18].

Coombs and Lehner [12] used distribution parameters as variables in the distributive model to test if moments of distributions are useful in assessing risk. For a lottery $(b + 2(1 - p)a, p; b - 2pa)$ (this means that the lottery has an outcome $(b + 2(1 - p)a)$ with probability p and an outcome $(b - 2pa)$, otherwise), which has a mean equal to b and range $2a$, the distributive model is represented by

$$R(a, b, p) = [\phi_1(a) + \phi_2(b)]\phi_3(p) \quad (1)$$

where R is a riskiness function and ϕ_1, ϕ_2 , and ϕ_3 are real-valued monotonic functions defined on a, b , and p , respectively. Coombs and Lehner [12] showed that the distributive model (1) is not acceptable as a descriptive model of risk judgment. They concluded that complex interactions between the properties of risky propositions prevent a simple polynomial expression of the variables a, b , and p , from capturing perceived riskiness.

Coombs and Lehner [19] further considered perceived risk as a direct function of outcomes and probabilities, with no intervening distribution parameters. They assumed a bilinear model. In the case

of just three outcomes (positive, negative, and zero), perceived risk is represented by the following model:

$$R(X) = \phi_1(p)\phi_2(w) + \phi_3(q)\phi_4(l) \quad (2)$$

where w and l represent the positive and negative outcomes, with probabilities p and q ($p + q = 1$), respectively; R and ϕ_i ($i = 1, 2, 3$, and 4) are real-valued functions and X represents the lottery. The model assumes that a zero outcome and its associated probability have no direct effect on perceived risk. The form of model (2) is similar to Prospect theory [20]. Coombs and Lehner’s [19] experiment supported the notion that perceived risk can be decomposed into contributions from good and bad components, and the bad components play a larger role than the good ones.

Pollatsek and Tversky’s Risk Theory

An important milestone in the study of perceived risk is the axiomatization of risk theory developed by Pollatsek and Tversky [4]. They assumed four axioms for a risk system: (a) weak ordering; (b) cancellation (or additive independence); (c) solvability; and (d) an Archimedean property. Let P denote a set of simple probability distributions or lotteries $\{X, Y, Z, \dots\}$ and $\geq_R$ be a binary risk relation (meaning at least as risky as). For convenience, we use X, Y , and Z to refer to random variables, probability distributions, or lotteries interchangeably. Pollatsek and Tversky showed that the four axioms imply that there exists a real-valued function R on P such that for lotteries X and Y : (i) $X \geq_R Y$ if and only if $R(X) \geq R(Y)$; (ii) $R(X \circ Y) = R(X) + R(Y)$, where “ $\circ$ ” denotes the binary operation of adding independent random variables; that is, the convolution of their density functions.

Pollatsek and Tversky considered three additional axioms: (e) positivity; (f) scalar monotonicity; and (g) continuity. These three additional axioms imply that R is a linear combination of mean and variance:

$$R(X) = -\theta \bar{X} + (1 - \theta)E[(X - \bar{X})^2] \quad (3)$$

where $0 < \theta < 1$.

However, the empirical validity of equation (3) was criticized by Coombs and Bowen [21] who showed that factors other than mean and variance,

such as skewness, affect perceived risk. In Pollatsek and Tversky's system of axioms, the continuity condition based on the central limit theorem is directly responsible for the form of the mean–variance model (3). Coombs and Bowen [21] showed that skewness impacts perceived risk even under multiple plays of a lottery, when the effect of the central limit theorem modifies the effect of skewness.

Another empirically questionable axiom is the additive independence condition, which says that, for X, Y , and Z in P , $X \geq_R Y$ if and only if $X \circ Z \geq_R Y \circ Z$. Fishburn [22] provides the following example of a setting where additive independence is unlikely to hold. Many people feel that a lottery $X = (\$1000, 0.01; -\$10\,000)$ (i.e., X has probability 0.01 of a \$1000 gain, and a \$10 000 loss otherwise) is riskier than $Y = (\$2000, 0.5; -\$12\,000)$. Consider another degenerate lottery Z that has a sure \$11 000 gain. Since $X \circ Z$ yields at least a \$1000 gain while $Y \circ Z$ results in a loss of \$1000 with probability 0.5, it seems likely that most people would consider $Y \circ Z$ to be riskier than $X \circ Z$. This risk judgment pattern is inconsistent with additive independence. Empirical studies have also failed to support the independence condition [23, 24].

Nevertheless, some of Pollatsek and Tversky's axioms, such as positivity and scalar monotonicity, are very appealing. Because they are important to the present article, we briefly introduce them here. According to the positivity axiom, if K is a degenerate lottery with an outcome $k > 0$, then $X \geq_R X \circ K$ for all X in P . In other words, the addition of a positive sure-amount to a lottery would decrease its perceived risk. This quality is considered an essential property of perceived risk and has been confirmed by several empirical studies (e.g. [9, 12]).

Another appealing axiom in Pollatsek and Tversky's theory is scalar monotonicity, which says, for all X, Y in P with $E(X) = E(Y) = 0$, (a) $\beta X \geq_R X$ for $\beta > 1$; (b) $X \geq_R Y$ if and only if $\beta X \geq_R \beta Y$ for $\beta > 0$. This axiom asserts that, for lotteries with zero expectation, risk increases when the lottery is multiplied by a real number $\beta > 1$ (also see [6]), and that the risk ordering is preserved upon a scale change of the lotteries (e.g., dollars to pennies). Pollatsek and Tversky regarded the positivity axiom and part (a) of the monotonicity axiom as necessary assumptions for any theory of risk.

In a more recent study, Rotar and Sholomitsky [25] weakened part (b) of the scalar monotonicity axiom (coupled with some other additional conditions) to arrive at a more flexible risk model that is a finite linear combination of cumulants of higher orders. This generalized risk model can take into account additional characteristics of distributions such as skewness and other higher-order moments. However, because Rotar and Sholomitsky's risk model still retains the additive independence condition as a basic assumption, their model would be subject to the same criticisms regarding the additivity of risk.

Luce's Risk Models and Others

Subsequent to the criticisms of Pollatsek and Tversky's risk measure, Luce [26] approached the problem of risk measurement in a different way. He began with a multiplicative structure of risk. First, Luce considered the effect of a change of scale on risk, multiplying all outcomes of a lottery by a positive constant. He assumed two simple possibilities, an additive effect and a multiplicative effect, presented as follows:

$$R(\alpha * X) = R(X) + S(\alpha) \quad (4)$$

or

$$R(\alpha * X) = S(\alpha) R(X) \quad (5)$$

where α is a positive constant and S is a strictly increasing function with $S(1) = 0$ for equation (4) and $S(1) = 1$ for equation (5). Luce's assumptions (4) and (5) are related to Pollatsek and Tversky's [4] scalar monotonicity axiom. However, an important difference is that Pollatsek and Tversky only applied this assumption to the lotteries with zero-expected values. As we see later, this may explain why Luce's models have not been supported by experiments.

Next, Luce considered two ways in which the outcomes and probabilities of a lottery could be aggregated into a single number. The first aggregation rule is analogous to the expected utility form and leads to an expected risk function:

$$R(X) = \int_{-\infty}^{\infty} T(x) f(x) dx = E[T(X)] \quad (6)$$

where T is some transformation function of the random variable X and $f(x)$ is the density of

lottery X . In the second aggregation rule, the density goes through a transformation before it is integrated,

$$R(X) = \int_{-\infty}^{\infty} T^+[f(x)] dx \quad (7)$$

where T^+ is some nonnegative transformation function. The combinations of the two decomposition rules (4) and (5) and the two aggregation rules (6) and (7) yield four possible measures of risk as follows:

1. by rules (4) and (6),

$$R(X) = a \int_{x \neq 0} \log |x| dx + b_1 \int_{-\infty}^0 f(x) dx + b_2 \int_0^{\infty} f(x) dx, \quad a > 0 \quad (8)$$

2. by rules (5) and (6),

$$R(X) = a_1 \int_{-\infty}^0 |x|^\theta dx + a_2 \int_0^{\infty} x^\theta dx, \quad \theta > 0 \quad (9)$$

3. by rules (4) and (7),

$$R(X) = -a \int_{-\infty}^{\infty} f(x) \log f(x) dx + b, \quad a > 0, b = 0 \quad (10)$$

4. by rules (5) and (7),

$$R(X) = a \int_{-\infty}^{\infty} f(x)^{1-\theta} dx, \quad a, \theta > 0 \quad (11)$$

Luce's risk models did not receive positive support from an experimental test by Keller *et al.* [9]. As Luce himself noted, an obvious drawback of models (10) and (11) is that both measures require that risk should not change if we add or subtract a constant amount to all outcomes of a lottery. This is counter to intuition and to empirical evidence [9, 12]. Luce's absolute logarithmic measure (equation 8) is also neither empirically valid [9] nor prescriptively valid [27]. In the experiment by Keller *et al.* [9], only the absolute power model (9) seems to have some promise as a measure of perceived risk.

Following Luce's work, Sarin [27] considered the observation that when a constant is added to all outcomes of a lottery, perceived risk should decrease.

He assumed that there is a strictly monotonic function S such that for all lotteries and any real number β ,

$$R(\beta \circ X) = S(\beta)R(X) \quad (12)$$

Together with the expectation principle (rule 6), this yields an exponential form of risk model,

$$R(X) = kE(e^{cX}) \quad (13)$$

where $kc < 0$.

Luce and Sarin's models employ the expectation principle, which was first postulated for risk by Huang [28]. The expectation principle – an application of the independence axiom of expected utility theory – means that the risk measure R is linear under convex combinations:

$$R(\lambda X + (1 - \lambda)Y) = \lambda R(X) + (1 - \lambda)R(Y) \quad (14)$$

where $0 < \lambda < 1$. Empirical studies have suggested that this assumption may not be valid for risk judgments [9, 19]. Weber and Bottom [10] showed, however, that the independence axiom is not violated for risk judgments, but that the culprit is the so-called probability accounting principle (see [29]). These findings cast doubt on any perceived-risk models based on the expectation principle, including Luce's logarithmic model (8) and power model (9), and Sarin's exponential model (13).

Sarin also generalized the simple expectation principle using Machina's [30] nonexpected utility theory and extended Luce's models (8 and 9) into more complicated risk models. However, since risk judgment is not identical to choice preference under risk, Sarin's proposal needs to be tested empirically.

Luce and Weber [29] proposed a revision of Luce's original power model (8) based on empirical findings. This conjoint expected risk (CER) model has the following form:

$$\begin{aligned} R(X) = & A_0 \Pr(X = 0) \\ & + A_+ \Pr(X > 0) + A_- \Pr(X < 0) \\ & + B_+ E[X^{K_+} | X > 0] \Pr(X > 0) \\ & + B_- E[|X|^{K_-} | X < 0] \Pr(X < 0) \end{aligned} \quad (15)$$

where A_0 , A_+ , and A_- are probability weights, and B_+ and B_- are weights of the conditional expectations, raised to some positive powers, K_+ and K_- . The major advantage of the CER model is that it

allows for asymmetric effects of transformations on positive and negative outcomes. Weber [31] showed that the CER model describes risk judgments reasonably well. One possible drawback of the CER model is that the lack of parsimony provides the degrees of freedom to fit any set of responses.

Weber and Bottom [10] tested the adequacy of the axioms underlying the CER model and found that the conjoint structure assumptions about the effect of change of scale transformations on risk hold for negative-outcome lotteries, but not for positive-outcome lotteries. This suggests that the multiplicative independence assumption (i.e., for positive (or negative)-outcome-only lotteries X and Y , $X \geq_R Y$ if and only if $\beta X \geq_R \beta Y$ for $\beta > 0$) may not be valid. Note that Pollatsek and Tversky's [4] scalar monotonicity axiom is identical to multiplicative independence, but is only assumed to hold for lotteries with zero-expected values.

Fishburn's Risk Systems

Fishburn [31, 32] explored risk measurement from a rigorous axiomatic perspective. In his two-part study on axiomatizations of perceived risk, he considered lotteries separated into gains and losses relative to a target, say 0. Then the general set P of measures can be written as $P = \{(\alpha, p; \beta, q) : \alpha \geq 0, \beta \geq 0, \alpha + \beta \leq 1, p \text{ in } P^-, q \text{ in } P^+\}$, where α is the loss probability, p is the loss distribution given a loss, β is the gain probability, q is the gain distribution given a gain, $1 - p - q$ is the probability for the target outcome 0, and P^- and P^+ are the sets of probability measures defined on loss and gain, respectively. The risk measure in this general approach satisfies $(\alpha, p; \beta, q) \geq_R (\gamma, r; \delta, s)$ if and only if $R(\alpha, p; \beta, q) \geq R(\gamma, r; \delta, s)$.

Fishburn assumed that there is no risk if and only if there is no chance of getting a loss, which implies $R = 0$ if and only if $\alpha = 0$. This rules out additive forms of risk measures like $R(\alpha, p; \beta, q) = R_1(\alpha, p) + R_2(\beta, q)$, but allows forms that are multiplicative in losses and gains; e.g., $R(\alpha, p; \beta, q) = \rho(\alpha, p) \times \tau(\beta, q)$. If ρ and τ are further decomposable, then the risk measure can be

$$R(\alpha, p; \beta, q) = \left[\rho_1(\alpha) \int_{x < 0} \rho_2(x) dp(x) \right] \times \left[1 - \tau_1(\beta) \int_{y > 0} \tau_2(y) dq(y) \right] \quad (16)$$

According to Fishburn [33], the first part of this model measures the "pure" risk involving losses and the second measures the effect of gains on the risk. In the multiplicative model (16), gains proportionally reduce risk independent of the particular (α, p) involved (unless the probability of a loss, α , is zero, in which case there is no risk to be reduced). Fishburn did not suggest functional forms for the free functions in his models, so it is difficult to test them empirically.

In summary, since the pioneering work of Coombs and his associates' on perceived risk, several formal theories and models have been proposed. But none of these risk models is fully satisfactory. As Pollatsek and Tversky [4] wrote, "... our intuitions concerning risk are not very clear and a satisfactory operational definition of the risk ordering is not easily obtainable." Nevertheless, empirical studies have observed a remarkable consistency in risk judgments [9, 10] suggesting the existence of robust measures of perceived risk.

Two-Attribute Models for Perceived Risk

In this section, we propose two-attribute models for perceived risk based on the mean of a lottery and the standard measure of risk that is discussed in another article in this collection (see **Axiomatic Measures of Risk and Risk-Value Models**). In particular, our measures of perceived risk can be incorporated into preference models based on the notion of risk-value trade-offs. For the purpose of application, we suggest several explicit functional forms for the measures of perceived risk.

A Two-Attribute Structure for Perceived Risk

A common approach in previous studies of perceived risk is to look for different factors underlying a lottery that are responsible for risk perceptions, such as mean and variance or other risk dimensions, and then consider some separation or aggregation rules to obtain a risk measurement model (see [34] for a review). Jia and Dyer [2] decomposed a lottery X into its mean $\bar{X}$ and its standard risk, $X' = X - \bar{X}$, and proposed a standard measure of risk based on expected utility theory:

$$R(X') = -E[u(X')] = -E[u(X - \bar{X})] \quad (17)$$

where $u(\cdot)$ is a von Neumann and Morgenstern [35] utility function. The mean of a lottery serves as a status quo for measuring the standard risk (see **Axiomatic Measures of Risk and Risk-Value Models**) for a summary of this development.

The standard measure of risk has many desirable properties that characterize the “pure” risk of lotteries. It can provide a suitable measure of perceived risk for lotteries with zero-expected values as well. However, the standard measure of risk would not be appropriate for modeling people’s perceived risk for general lotteries since the standard measure of risk is independent of expected value or any certain pay-offs. That is, if $Y = X + k$, where k is a constant, then $Y' = Y - \bar{Y} = X - \bar{X} = X'$. As we discussed earlier, empirical studies have shown that people’s perceived risk decreases as a positive constant amount is added to all outcomes of a lottery.

To incorporate the effect of the mean of a lottery on perceived risk, we consider a two-attribute structure for evaluating perceived risk; that is, $(\bar{X}, X')$. In fact, a lottery X can be represented by its expected value $\bar{X}$ and the standard risk X' exclusively, e.g., $X = \bar{X} + X'$. Thus, $(\bar{X}, X')$ is a natural extension of the representation of the lottery X . This two-attribute structure has an intuitive interpretation in risk judgment. When people make a risk judgment, they may first consider the variation or uncertainty of the lottery, measured by X' , and then take into account the effect of expected value on the uncertainty perceived initially, or *vice versa*.

To develop our measure of perceived risk formally, let $\mathbf{P}$ be the set of all simple probability distributions, including degenerate distributions, on a nonempty product set, $\mathbf{X}_1 \times \mathbf{X}_2$, of outcomes, where $\mathbf{X}_i \subseteq \text{Re}$, $i = 1, 2$, and Re is the set of real numbers. For our special case, the outcome of a lottery X on $\mathbf{X}_1$ is fixed at its mean $\bar{X}$; thus, the marginal distribution on $\mathbf{X}_1$ is degenerate with a singleton outcome $\bar{X}$. Because $\bar{X}$ is a constant, the two “marginal distributions” $(\bar{X}, X')$ are sufficient to determine a unique distribution in $\mathbf{P}$.

Let $>_{\bar{R}}$ be a strict risk relation, $\sim_{\bar{R}}$ an indifference risk relation, and $\geq_{\bar{R}}$ a weak risk relation on $\mathbf{P}$. We assume a two-attribute case of the expectation principle and other necessary conditions analogous to those of multiattribute utility theory (e.g., see [36, 37]) for the risk ordering $>_{\bar{R}}$ on $\mathbf{P}$, such that for all $(\bar{X}, X'), (\bar{Y}, Y') \in \mathbf{P}$, $(\bar{X}, X') >_{\bar{R}} (\bar{Y}, Y')$ if and only if $R_p(\bar{X}, X') > R_p(\bar{Y}, Y')$, where R_p is defined as

follows:

$$R_p(\bar{X}, X') = E[U_R(\bar{X}, X')] \quad (18)$$

and U_R is a real-valued function unique up to a positive linear transformation. Note that because the marginal distribution for the first attribute is degenerate, the expectation, in fact, only needs to be taken over the marginal distribution for the second attribute, which, in turn, is the original distribution of a lottery X normalized to a mean of zero.

Basic Forms of Perceived-Risk Models

Model (18) provides a general measure of perceived risk based on two attributes, the mean and standard risk of a lottery. To obtain separable forms of perceived-risk models, we make the following assumptions about risk judgments.

Assumption 1. For $X', Y' \in \mathbf{P}^0$, if there exists a $w^o \in \text{Re}$ for which $(w^o, X') >_{\bar{R}} (w^o, Y')$, then $(w, X') >_{\bar{R}} (w, Y')$ for all $w \in \text{Re}$.

Assumption 2. For $X', Y' \in \mathbf{P}^0$, $(0, X') >_{\bar{R}} (0, Y')$ if and only if $X' >_R Y'$.

Assumption 3. For $(\bar{X}, X') \in \mathbf{P}$, then $(\bar{X}, X') >_{\bar{R}} (\bar{X} + \Delta, X')$ for any constant $\Delta > 0$.

Assumption 1 is an independence condition, which says that the risk ordering for two lotteries with the same mean will not switch when the common mean changes to any other value. Compared with Pollatsek and Tversky’s [4] additive independence condition, Assumption 1 is weaker since it features a pair of lotteries with the same mean and a common constant rather than a common lottery. Coombs [8] considered a similar assumption for a riskiness ordering; i.e., $X \geq_R Y$ if and only if $X + k \geq_R Y + k$, where $E(X) = E(Y)$ and k is a constant. However, our formulation is based on a two-attribute structure, which leads to a separable risk function for $\bar{X}$ and X' , as we shall discuss.

Assumption 2 postulates a relationship between the two risky binary relations, $>_{\bar{R}}$ and $>_R$ (where $>_R$ is a strict risk relation on $\mathbf{P}^0$), so that for any zero-expected lotteries, the risk judgments made by $R_p(0, X')$ and by the standard measure of risk $R(X')$ are consistent. The last assumption implies that if two lotteries have the same “pure” risk, X' , then the lottery with a larger mean will be perceived less

risky than the one with a lower mean as suggested by previous studies (e.g. [9, 12]).

Result 1 [38]. The two-attribute perceived-risk model (18) can be decomposed into the following form:

$$R_p(\bar{X}, X') = g(\bar{X}) + \psi(\bar{X})R(X') \quad (19)$$

if and only if assumptions 1–3 are satisfied, where $\psi(\bar{X}) > 0$, $g'(\bar{X}) < -\psi'(\bar{X})R(X')$, and $R(X')$ is the standard measure of risk.

According to this result, perceived risk can be constructed by a combination of the standard measure of risk and the effect of the mean. Result 1 postulates a constraint on the choice of functions $g(\bar{X})$ and $\psi(\bar{X})$ in model (19). If $\psi(\bar{X})$ is a constant, then the condition $g'(\bar{X}) < -\psi'(\bar{X})R(X')$ becomes $g'(\bar{X}) < 0$; i.e., $g(\bar{X})$ is a decreasing function of $\bar{X}$. Otherwise, a nonincreasing function $g(\bar{X})$ and a decreasing function $\psi(\bar{X})$ should be sufficient to satisfy the condition $g'(\bar{X}) < -\psi'(\bar{X})R(X')$ when $R(X') > 0$.

For risk judgments, we may require that any degenerate lottery should have no risk (e.g., [39–41]). The concept of risk would not be evoked under conditions of certainty; no matter how bad a certain loss may be, it is a sure thing and, therefore, riskless. This point of view can be represented by the following assumption.

Assumption 4. For any $w \in \text{Re}$, $(w, 0) \sim_{\bar{R}} (0, 0)$.

Result 2 [38]. The two-attribute perceived-risk model (19) can be represented as follows:

$$R_p(\bar{X}, X') = \psi(\bar{X})[R(X') - R(0)] \quad (20)$$

if and only if assumptions 1–4 are satisfied, where $\psi(\bar{X}) > 0$ is a decreasing function of the mean $\bar{X}$, $\psi(\bar{X})[R(X') - R(0)]$ is the standard measure of risk, and $R(0) = -u(0)$ is a constant.

When $g(\bar{X}) = -R(0)\psi(\bar{X})$ as required by Assumption 4, the general risk model (19) reduces to the multiplicative risk model (20). This multiplicative risk model captures the effect of the mean on perceived riskiness in an appealing way; increasing (decreasing) the mean reduces (increases) perceived riskiness in a proportional manner.

Finally, note that the two-attribute perceived-risk models (19) and (20) are not simple expected forms; we decompose a lottery into a two-attribute structure and only assume the expectation principle holds for normalized lotteries with zero-expected values. For general lotteries with non zero-expected values, the

underlying probabilities of lotteries can influence the standard measure of risk in a nonlinear fashion via $g(\bar{X}) = -R(0)\psi(\bar{X})$, $\psi(\bar{X})$. Thus, models (19) and (20) avoid the drawbacks of expected risk models because the two-attribute expected utility axioms will not generally result in linearity in probability in the perceived-risk models.

Relationship between Perceived Risk and Preference

An important feature of the two-attribute approach to modeling risk is that the derived measures of perceived risk can be treated as a stand alone primitive concept and can also be incorporated into preference models in a clear fashion. As summarized in the complementary article, we proposed a risk-value theory for preference modeling also by decomposing a lottery into a two-attribute structure, the mean of the lottery, and its standard risk (see **Axiomatic Measures of Risk and Risk-Value Models**).

A general form of the risk-value model can be represented as follows:

$$\bar{X} - \phi(\bar{X})[R(X') - R(0)] \quad (21)$$

where $f(\bar{X}, X')$ represents a preference function based on the mean of a lottery and its standard risk, $V(\bar{X})$ is a subjective value measure for the mean of a lottery, $\phi(\bar{X}) > 0$ is a trade-off factor that may depend on the mean, and the other notations are the same as in equation (20). In general, a decreasing trade-off factor $\phi(\bar{X})$ is required in risk-value theory, which implies that the intensity of the risk effect on preference decreases as a positive constant amount is added to all outcomes of a lottery. Since the risk-value model (21) is based on the two-attribute expected utility axioms, and the perceived-risk model (19) is derived by using the reverse interpretation of the same axioms, the two types of models must be a negative linear transformation of each other, i.e., $\bar{X} - \phi(\bar{X})[R(X') - R(0)]R_p(\bar{X}, X')$, where $a > 0$ and b are constants. Several previously proposed measures of perceived risk also have the implication that their converse forms may be used for preference modeling (e.g. [4, 27, 30]).

The relationships between the functions in models (19) and (21) can be clarified by transforming the perceived-risk model (19) into another representation similar to the risk-value model (21).

When $X = \bar{X}$, equation (19) becomes $R_p(\bar{X}, X') = g(\bar{X}) + \psi(\bar{X})R(X')$. Let $h(\bar{X}) = R_p(\bar{X}, X')$, then $g(\bar{X}) = g(\bar{X}) + \psi(\bar{X})R(X')$. Substituting this into equation (19), we obtain an alternative representation of the perceived-risk measure, $R_p(\bar{X}, X') = g(\bar{X}) + \psi(\bar{X})R(X')$. On the basis of our risk-value theory (result 1), we can have $h(\bar{X}) = -aV(\bar{X}) + b$, and $\psi(\bar{X}) = a\phi(\bar{X})$, where $a > 0$ and b are constants.

The measure of perceived risk (equation 20) has more intuitive appeal in constructing preference based on risk-value trade-offs. Substituting $\phi(\bar{X}) = (1/a)\psi(\bar{X})$ into equation (21), we have $\bar{X} - \phi(\bar{X})[R(X') - R(0)] = V(\bar{X}) - (1/a)\psi(\bar{X})[R(X') - R(0)] = R_p(\bar{X}, X')$. This representation is consistent with an explicit trade-off between perceived risk and value in risky decision making. This provides a clear link between a riskiness ordering and a preference ordering, and shows an explicit role of risk perceptions in decision making under risk.

Some Examples

When $g(\bar{X})$ is linear, $\psi(\bar{X})$ is constant, and $R(X')$ is the variance, the risk model (19) reduces to Pollatsek and Tversky's [4] mean–variance model (1), as a special case. But Pollatsek and Tversky's risk model may be considered oversimplified. To obtain Rotar and Sholomitsky's [25] generalized moments model, the standard measure of risk should be based on a polynomial utility model.

We can select some appropriate functional forms for $g(\bar{X})$, $\psi(\bar{X})$, and $R(X')$ to construct specific instances of equation (19). In **Axiomatic Measures of Risk and Risk-Value Models**, we have proposed some explicit models for the standard measure of risk $R(X')$. Those models can be used directly in constructing functional forms of perceived-risk models (19) and (20). An example for $\psi(\bar{X})$ is $\psi(\bar{X}) = ke^{-b\bar{X}}$, where $k > 0$ and $b \geq 0$ (when $b = 0$, $\psi(\bar{X})$ becomes a constant k), and a simple choice for $g(\bar{X})$ is $g(\bar{X}) = -a\bar{X}$, where $a > 0$ is a constant. Some functional forms of the perceived-risk model (19) based on these choices of $\psi(\bar{X})$ and $g(\bar{X})$ are the following:

$$R_p(\bar{X}, X') = -a\bar{X} + ke^{-b\bar{X}}E[e^{-c(X-\bar{X})}] \quad (22)$$

$$R_p(\bar{X}, X') = -a\bar{X} + ke^{-b\bar{X}}\{E[(X - \bar{X})^2] - cE[(X - \bar{X})^3]\} \quad (23)$$

$$R_p(\bar{X}, X') = -a\bar{X} + e^{-b\bar{X}}\{dE^- [|X - \bar{X}|^{\theta_2}] - eE^+ [|X - \bar{X}|^{\theta_1}]\} \quad (24)$$

where $a, b, c, d, e, k, \theta_1$, and θ_2 are constants, $E^- [|X - \bar{X}|^{\theta_2}] = \sum_{x_i < \bar{X}} p_i |x_i - \bar{X}|^{\theta_2}$, $E^+ [|X - \bar{X}|^{\theta_1}] = \sum_{x_i > \bar{X}} p_i (x_i - \bar{X})^{\theta_1} = \sum_{x_i > \bar{X}} p_i (x_i - \bar{X})^{\theta_1}$, and p_i is the probability associated with the outcome x_i . When $b = 0$, these perceived-risk models become additive forms. For consistency with their corresponding risk-value models, we refer to equation (22) as the exponential risk model, equation (23) as the moments risk model, and equation (24) as the disappointment risk model. The latter was introduced by Bell [42] and explored in more detail by Jia *et al.* [43].

Similarly, some examples of the multiplicative form of risk model (20) are given as follows:

$$R_p(\bar{X}, X') = ke^{-b\bar{X}}E[e^{-c(X-\bar{X})} - 1] \quad (25)$$

$$R_p(\bar{X}, X') = ke^{-b\bar{X}}\{E[(X - \bar{X})^2] - cE[(X - \bar{X})^3]\} \quad (26)$$

$$R_p(\bar{X}, X') = e^{-b\bar{X}}\{dE^- [|X - \bar{X}|^{\theta_2}] - eE^+ [|X - \bar{X}|^{\theta_1}]\} \quad (27)$$

Research on financial risk and psychological risk (i.e., perceived risk) has been conducted separately in the past. The risk-value framework is able to provide a unified approach for dealing with both types of risk. The standard measure of risk is more normative in nature and should be useful in financial modeling. For instance, the standard measure of risk in perceived-risk models (24) and (27) includes many financial risk measures as special cases [2]. Our perceived-risk models show how financial measures of risk and psychological measures of risk can be related. In particular, for a given level of the mean value, minimizing the perceived risk will be equivalent to minimizing the standard risk since the expressions for $g(\bar{X})$ and $\psi(\bar{X})$ in equation (19) become constants. Our measures of perceived risk provide a clear way to simplify the decision criterion of minimizing perceived risk as suggested, but never operationalized, in Coombs' portfolio theory.

Conclusions

In this article, we have reviewed previous studies about perceived risk and focused on a two-attribute structure for perceived risk based on the mean of a lottery and its standard risk. Some of these risk measures also take into account the asymmetric effects of losses and gains on perceived risk. These measures of perceived risk can unify a large body of empirical evidence about risk judgments, and are consistent with the stylized facts regarding risk judgments listed in the introduction. For more details regarding the flexibility provided by the two-attribute structure for perceived risk see Jia *et al.* [38]; for details on the empirical validity of the assumptions behind the models, see Butler *et al.* [44].

In particular, these measures of perceived risk show a clear relationship between financial measures of risk and psychological measures of risk. They can also be incorporated into preference models in a natural way, on the basis of a trade-off between perceived risk and expected value. This shows an intuitively appealing connection between perceived risk and preference.

This development uses the expected value of a lottery as the reference point regarding the measures of perceived risk. The expected value is a convenient and probabilistically appealing reference point [2], which makes our risk models mathematically tractable and practically usable. There are other possible reference points that might be considered, such as an aspiration level, a reference lottery, or some other external reference point, such as zero. It would be interesting to consider these alternative reference points in our measures of perceived risk in future research.

Acknowledgment

This article summarizes a stream of research on perceived risk. In particular, we have incorporated materials that appeared previously in Jia J, Dyer JS, Butler JC. Measures of perceived risk. *Management Science* 1999 **45**: 519–532.

Basic Concepts of Insurance

Insurance is an economic institution that allows the transfer of financial risk from an individual to a pooled group of risks by means of a two-party contract. The insured party obtains a specified amount of coverage against an uncertain event (e.g., an earthquake or flood) for a smaller but certain payment (the premium). Insurers may offer fixed, specified coverage or replacement coverage, which takes into account the increased cost of putting the structure back to its original condition.^a

Most insurance policies have some form of deductible, which means that the insured party must cover the first portion of their loss. For example, a 10% deductible on a \$100 000 earthquake policy means that the insurer is responsible for property damage that exceeds \$10 000 up to some prespecified maximum amount, the coverage limit.

Losses and Claims

The insurance business, like any other business, has its own vocabulary. A *policyholder* is a person who has purchased insurance. The term *loss* is used to denote the payment that the insurer makes to the policyholder for the damage covered under the policy. It is also used to mean the aggregate of all payments in one event. Thus, we can say that there was a “loss” under the policy, meaning that the policyholder received a payment from the insurer. We may also say that the industry “lost” \$12.5 billion dollars in the Northridge earthquake.

A *claim* means that the policyholder is seeking to recover payments from the insurer for damage under the policy. A claim does not result in a *loss* if the amount of damage is below the deductible, or subject to a policy exclusion, but there still are expenses in investigating the claim. Even though there is a distinction between a claim and a loss, the terms are often used interchangeably to mean that an insured event occurred, or with reference to the prospect of having to pay out money.

The Law of Large Numbers

Insurance markets can exist because of *the law of large numbers* which states that for a series of independent and identically distributed random variables (such as automobile insurance claims), the variance of the average amount of a claim payment decreases as the number of claims increases. Consider the following gambling example. If you go to Las Vegas and place a bet on roulette, you are expected to lose a little more than 5 cents every time you bet \$1. But each time you bet, you either win or lose whole dollars. If you bet ten times, your average return is your net winnings and losses divided by ten. According to the law of large numbers, the average return converges to a loss of 5 cents per bet. The larger the number of bets, the closer the average loss per bet is to 5 cents.

Fire is an example of a risk that satisfies the law of large numbers since its losses are normally independent of one another.^b To illustrate this, suppose that an insurer wants to determine the accuracy of the fire loss for a group of identical homes valued at \$100 000, each of which has a 1/1000 annual chance of being completely destroyed by fire. If only one fire occurs in each home, the expected annual loss for each home would be \$100 (i.e., $1/1000 \times \$100\,000$).

If the insurer issued only a single policy, then a variance of approximately \$100 would be associated with its expected annual loss.^c

As the number of issued policies, n , increases the variance of the expected annual loss or mean decreases in proportion to n . Thus, if $n = 10$, the variance of the mean is approximately \$10. When $n = 100$ the variance decreases to \$1, and with $n = 1000$ the variance is \$0.10. It should thus be clear that it is not necessary to issue a large number of policies to reduce the variability of expected annual losses to a very small number if the risks are independent.

However, natural hazards – such as earthquakes, floods, hurricanes, and conflagrations such as the Oakland fire of 1991 – create problems for insurers because the risks affected by these events are not independent. They are thus classified as *catastrophic risks*. If a severe earthquake occurs in Los Angeles, there is a high probability that many structures would be damaged or destroyed at the same time. Therefore, the variance associated with an individual loss is actually the variance of all of the losses that occur from the specific disaster. Because of this high

variance, it takes an extraordinarily long history of past disasters to estimate the average loss with any degree of predictability. This is why seismologists and risk assessors would like to have databases of earthquakes, hurricanes, or other similar disasters over 100- to 500-year periods. With the relatively short period of recorded history, the average loss cannot be estimated with any reasonable degree of accuracy.

One way that insurers reduce the magnitude of their catastrophic losses is by employing high deductibles, where the policyholder pays a fixed amount of the loss (e.g., the first \$1000) or a percentage of the total coverage (e.g., the first 10% of a \$100 000 policy). The use of coinsurance, whereby the insurer pays a fraction of any loss that occurs, produces an effect similar to a deductible. Another way of limiting potential losses is for the insurer to place caps on the maximum amount of coverage on any given piece of property.

An additional option is for the insurer to buy reinsurance. For example, a company might purchase a reinsurance contract that covers any aggregate insured losses from a single disaster that exceeds \$50 million up to a maximum of \$100 million. Such an excess-of-loss contract could be translated as follows: the insurer would pay for the first \$50 million of losses, the reinsurer the next \$50 million, and the insurer the remaining amount if total insured losses exceeding \$100 million. An alternative contract would be for the insurer and reinsurer to share the loss above \$50 million, prorated according to some predetermined percentage.

End Notes

- ^a. This paper is based on material in Kunreuther [1].
- ^b. The Oakland fire of October 20, 1991 is a notable exception with 1941 single-unit dwellings totally damaged and 2069 partially destroyed with a total insured loss of \$1.7 billion. The October 1996 wild-fires that destroyed a number of homes in the Los Angeles area at a cost of many millions of dollars is another example of a nonindependent set of events.
- ^c. The variance for a single loss L with probability p is $Lp(1 - p)$. If $L = \$100\,000$ and $p = 1/1000$, then $Lp(1 - p) = \$100\,000 (1/1000)(999/1000)$, or \$99.90.

Bayes' Theorem and Updating of Belief

Basic Concepts

In statistics, we are concerned with the deductions that can be made from one or more observations about a hypothesis. This could involve a choice between a number of discrete alternatives, which includes hypothesis testing as a particular case, or choosing which value of an unknown quantity is best supported by the evidence, which is estimation theory. In *Bayesian statistics* (see **Bayesian Statistics in Quantitative Risk Assessment**), all such problems are dealt with by the use of Bayes' theorem.

Bayes' theorem is named after the Reverend Thomas Bayes (1702–1761), who studied how to compute a distribution for the parameter of a binomial distribution (to use modern terminology). His work, which makes use of a particular case of the theorem, was published posthumously in 1763 [1]. Pierre-Simon, Marquis de Laplace replicated and extended these results and was the first person to state the theorem in a way that is easily recognizable today (see [2]).

An example that illustrates the techniques involved comes from the consideration of a simplified version of the situation just before the time of the British national referendum as to whether the United Kingdom should remain part of the European Economic Community (EEC) that was held in 1975. Suppose that at that date, which was shortly after an election that the Labour Party had won, the proportion of the electorate supporting Labour (L) stood at 52%, while the proportion supporting the Conservatives (C) stood at 48% (it being assumed for simplicity that support for all other parties was negligible, although this was far from being the case). There were many opinion polls taken at the time, so we can take it as known that 55% of Labour supporters and 85% of Conservative voters intended to vote "Yes" (Y) and the remainder intended to vote "No" (N). Suppose that knowing all this you met someone at the time who said that she intended to vote "Yes", and you were interested in knowing which political party she supported. Using the notation $\Pr(A|B)$ to mean the probability of A , given B , we can summarize the information available by saying that

$$\Pr(L) = 0.52, \Pr(Y|L) = 0.55$$

$$\Pr(C) = 0.48, \Pr(Y|C) = 0.85 \quad (1)$$

(In view of present-day disenchantment with the EEC on many sides these figures may surprise many who were not around at the time, but they are in fact not wholly unrealistic.) What we want to do is to reverse the conditioning and find expressions for $\Pr(L|Y)$ and $\Pr(C|Y)$, and it is exactly this sort of problem that Bayes' theorem is designed to deal with.

The development of the theorem results from the definition of conditional probability. Given two events A and B , we define the intersection $A \cap B$ of them as happening when both of them occur, so in the above example $L \cap Y$ occurs when we find someone who is a Labour voter who also intends to vote "Yes" in the referendum. The formal definition of the conditional probability of A , given B , is then

$$\Pr(A|B) = \frac{\Pr(A \cap B)}{\Pr(B)} \quad (2)$$

In some circumstances the probability of an event can be approximated by the relative frequency with which it occurs in a large number of trials, so if $\#(A)$ denotes the number of occurrences of A among $\#(T)$ trials,

$$\Pr(A) = \text{"lim"} \#(A)/\#(T) \quad (3)$$

as $\#(T)$ tends to infinity. We can then see that

$$\begin{aligned} \frac{\Pr(A \cap B)}{\Pr(B)} &= \frac{\text{"lim"} \#(A \cap B)/\#(T)}{\text{"lim"} \#(B)/\#(T)} \\ &= \text{"lim"} \#(A \cap B)/\#(B) \end{aligned} \quad (4)$$

which is the relative frequency with which A occurs if we restrict ourselves solely to those occasions on which B occurs, and thus it seems reasonably interpretable as the probability of A , given B . It should be clearly understood that there is nothing controversial about Bayes' theorem as such. It is frequently used by probabilists and statisticians, whether or not they are Bayesians. The distinctive feature of Bayesian statistics is the application of the theorem in a wider range of circumstances than is usual in classical statistics. In particular, Bayesian statisticians are always willing to talk of the probability of a hypothesis, both unconditionally (its *prior probability*) and given some evidence (its *posterior probability*), whereas other statisticians will only talk of the probability of a hypothesis in restricted circumstances.

Next observe that if two events A and B are disjoint, so that they both cannot occur together, or symbolically their intersection is null, denoted $A \cap B = \emptyset$, then the probability that one or the other occurs is the sum of their separate probabilities, that is,

$$\Pr(A \cup B) = \Pr(A) + \Pr(B) \quad (5)$$

More generally, if there are a number of events A_i , which are disjoint, that is, such that no two of which can occur simultaneously, then the probability that one or the other of them occurs is the sum of their separate probabilities, that is,

$$\Pr(\cup A_i) = \sum \Pr(A_i) \quad (6)$$

Further if these events are exhaustive, so that it is necessarily the case that one of them occurs, then

$$1 = \Pr(\cup A_i) = \sum \Pr(A_i) \quad (7)$$

Now consider any one event E and a set of disjoint events H_i , which are such that, one or the other of them is bound to occur. As the events H_i are disjoint, so are the events $E \cap H_i$, and hence (since if E occurs one of the events $E \cap H_i$ must occur)

$$\begin{aligned} \Pr(E) &= \Pr(E \cap H_i) \\ &= \sum \Pr(E \cap H_i) \end{aligned} \quad (8)$$

Now using the definition of conditional probability we see that

$$\Pr(E) = \sum \Pr(E|H_i) \Pr(H_i) \quad (9)$$

This result is sometimes called the *generalized addition law* or the *law of the extension of the conversation*.

Bayes' Theorem

We can now come to Bayes' theorem. With E and H_i as above, we can use the definitions of $\Pr(H_i|E)$ and $\Pr(E|H_i)$ to see that

$$\begin{aligned} \Pr(H_i|E) \Pr(E) &= \Pr(E \cap H_i) \\ &= \Pr(H_i) \Pr(E|H_i) \end{aligned} \quad (10)$$

from which it follows that

$$\Pr(H_i|E) \propto \Pr(H_i) \Pr(E|H_i) \quad (11)$$

This is one form of *Bayes' theorem*. We note that it can be used to find the probability of a hypothesis,

given some evidence from the probability of the same hypothesis before the evidence was adduced, and the probability of the evidence given that hypothesis. In words it can be remembered as

Posterior probability $\propto$

$$\text{Prior probability} \times \text{Likelihood} \quad (12)$$

where the word *likelihood* is applied to the conditional probability of E given H_i considered as a function of H_i for a fixed E . The reason for using a different word is that, so considered, its properties are different in that, for example, it is not necessarily the case that if we add $\Pr(E|H_i)$ over an exclusive and exhaustive collection of events the sum is unity – in an extreme case the value of $\Pr(E|H_i)$ can even be the same for all i so that the sum might be less than one or even diverge to infinity.

If we go back to the original political example, we see that we can deduce that

$$\Pr(L|Y) \propto \Pr(Y|L) \Pr(L),$$

$$\Pr(C|Y) \propto \Pr(Y|C) \Pr(C) \quad (13)$$

so that

$$\Pr(L|Y) \propto (0.55)(0.52) = 0.286,$$

$$\Pr(C|Y) \propto (0.85)(0.48) = 0.408 \quad (14)$$

Since $\Pr(L|Y) + \Pr(C|Y) = 1$ as we have supposed all involved are either Labour or Conservative supporters, we can deduce that

$$\begin{aligned} \Pr(L|Y) &= \frac{0.286}{(0.286 + 0.408)} \\ &= 0.41 \end{aligned} \quad (15)$$

(Note that while it is sensible to retain additional decimal places in intermediate calculations, it is not good practice to quote the end result with more precision than the original data.)

It is sometimes useful to think of Bayes' theorem in a form which employs a sign of equality rather than one of proportionality as

$$\Pr(H_i|E) = \frac{\Pr(H_i) \Pr(E|H_i)}{\sum_j \Pr(H_j) \Pr(E|H_j)} \quad (16)$$

in which case the denominator

$$\sum_j \Pr(H_j) \Pr(E|H_j) \quad (17)$$

is referred to as the *normalizing factor*, but, as we saw above, it normally suffices to remember it in the form with a proportionality sign.

We defined likelihood above as the conditional probability of E , given H_i considered as a function of H_i for a fixed E . It is, however, worth noting that since we can always use Bayes' theorem with a proportionality sign, it makes no difference if we multiply the likelihood by any constant factor. For this reason, we can generalize the definition of likelihood by saying that it is any constant multiple of the said conditional probability.

Bayes' Theorem for Random Variables

There is also a version of Bayes' theorem for random variables. If we have two random variables X and Y with joint probability density function $f_{X,Y}(x, y)$, then we can define the conditional density of Y given X as

$$f_{Y|X}(y|x) = \frac{f_{X,Y}(x, y)}{f_X(x)} \quad (18)$$

where the marginal density $f_X(x)$ can of course be evaluated as

$$f_X(x) = \int f_{X,Y}(x, y) dy \quad (19)$$

Similarly we can define the conditional density of X , given Y . Very similar arguments to those used above give us *Bayes' theorem for random variables* in the form

$$f_{Y|X}(y|x) \propto f_Y(y) f_{X|Y}(x|y) \quad (20)$$

Just as in the discrete case we think of $f_Y(y)$ as the prior density for X while $f_{Y|X}(y|x)$ is the posterior density for Y , given X , and $f_{X|Y}(x|y)$ is the likelihood. As in the discrete case, we can redefine the likelihood to be any constant multiple of this or indeed any multiple that depends on x but not on y . In this case the normalizing factor takes the form

$$\begin{aligned} f_X(x) &= \int f_{X,Y}(x, y) dy \\ &= \int f_Y(y) f_{X|Y}(x|y) dy \end{aligned} \quad (21)$$

A somewhat artificial example of the use of this formula in the continuous case is as follows. Suppose Y is the time before the first occurrence of a radioactive decay, which is measured by an instrument, but that, because there is a delay built into the mechanism, the decay is recorded as having

taken place at a time $X > Y$. We actually observe that the value of X is, say, x , but would like to say what we can about the value of Y on the basis of this knowledge. We might, for example, have

$$f_Y(y) = \exp(-y) \quad (22)$$

$$f_{X|Y}(x|y) = \exp\{-k(x - y)\} \quad (23)$$

for $0 < y < \infty$ and $y < x < \infty$. Then the required conditional density is given by

$$f_{Y|X}(y|x) \propto f_Y(y) f_{X|Y}(x|y) \quad (24)$$

$$\propto \exp\{-(k - 1)y\} \quad (25)$$

for $0 < y < x$. Often we will find that it is enough to get a result up to a constant of proportionality, but if we need the constant it is very easy to find it because we know that the integral (or the sum in the discrete case) must be one. Thus in this case

$$f_{Y|X}(y|x) = \frac{(k - 1) \exp\{-(k - 1)y\}}{\exp\{-(k - 1)x\} - 1} \quad (26)$$

for $0 < y < x$.

The example above concerns continuous random variables, but the same results are obtained in the case of discrete random variables if we interpret the density $f_X(x)$ as the probability mass function, that is, the probability $\Pr(X = x)$ that X takes the value x and similarly for the other densities.

We also encounter cases where we have two random variables, one of which is continuous and the other is discrete. All the above definitions and formulae extend in an obvious way to such a case provided we are careful, for example, to use integration for continuous variables but summation for discrete variables. In particular, the formulation

$$f_{Y|X}(y|x) \propto f_Y(y) f_{X|Y}(x|y) \quad (27)$$

is still valid.

It may help to consider an example (again a somewhat artificial one). Suppose k is the number of successes in n Bernoulli trials, so k has a binomial distribution of index n and parameter p , but that the value of p is unknown, your beliefs about it being uniformly distributed over the interval $[0, 1]$ of possible values. Then for $k = 0, 1, \dots, n$

$$f_{K|P}(k|p) = C_k^n p^k (1 - p)^{n-k} \quad (28)$$

$$f_P(p) = 1 \quad (0 \leq p \leq 1) \quad (29)$$

so that

$$\begin{aligned} f_{P|K}(p|k) &\propto f_P(p) f_{K|P}(k|p) \\ &= C_k^n p^k (1-p)^{n-k} \end{aligned} \quad (30)$$

$$\propto p^k (1-p)^{n-k} \quad (31)$$

The constant can be found by integration if it is required. It turns out that, given k , p has a beta distribution $\text{Be}(k+1, n-k+1)$, and that the normalizing constant is the reciprocal of the beta function $B(k+1, n-k+1)$. Thus, this beta distribution should represent your beliefs about p after you have observed k successes in n trials. This example has a special importance in that it is the one that Bayes himself discussed in the article mentioned below.

Sequential Use of Bayes' Theorem

It should be noted that Bayes' theorem is often used sequentially, starting from a prior distribution and using some data to produce a posterior distribution, which takes this data into account and then using this distribution as a prior one for further analysis, which takes into account further data, and so on. As an illustration of this process, in the example about the probability of success in Bernoulli trials discussed above, we can take the posterior density proportional to $p^k(1-p)^{n-k}$ as a prior for use when further observations are available. So if j is the number of successes in further m trials, then using the old posterior as the new prior results in a posterior

$$\begin{aligned} f_{P|J,K}(p|j, k) &\propto f_{P|K}(p|k) f_{J|P}(j|p) \\ &\propto p^k (1-p)^{n-k} C_j^m p^j (1-p)^{m-j} \\ &\propto p^{j+k} (1-p)^{m+n-j-k} \end{aligned} \quad (32)$$

Note that the result is just the same as if we had taken the original, uniform, prior distribution $f_P(p) = 1$ and looked for a posterior resulting from the observation of $j+k$ successes in $m+n$ trials.

It could also happen that you have prior beliefs about the value of the unknown parameter p , which are equivalent to having observed k successes in n trials, although you may not, in fact, have observed such trials. If this is so, and you then observe j successes in m trials, then of course the end result is just as found above, since

$$\begin{aligned} f_{P|J}(p|j) &\propto f_P(p) f_{J|P}(j|p) \\ &= p^k (1-p)^{n-k} C_j^m p^j (1-p)^{m-j} \\ &\propto p^{j+k} (1-p)^{m+n-j-k} \end{aligned} \quad (33)$$

The details differ but the basic methodology is the same when other distributions are involved.

Fuller accounts of the topics discussed above can be found in [3–5] or [6] (listed in approximate order of sophistication and mathematical difficulty).

Bayesian Analysis and Markov Chain Monte Carlo Simulation

Overview of Main Concepts

Bayesian analysis offers a way of dealing with information conceptually different from all other statistical methods. It provides a method by which observations are used to update estimates of the unknown parameters of a statistical model. With the Bayesian approach, we start with a parametric model that is adequate to describe the phenomenon we wish to analyze. Then, we assume a *prior distribution* for the unknown parameters θ of the model which represents our previous knowledge or belief about the phenomenon before observing any data. After observing some data assumed to be generated by our model we update these assumptions or beliefs. This is done by applying *Bayes' theorem* to obtain a *posterior probability density* for the unknown parameters given by

$$p(\theta|x) = \frac{p(x|\theta)p(\theta)}{\int p(x|\theta)p(\theta) d\theta} \quad (1)$$

where θ is the vector of unknown parameters governing our model, $p(\theta)$ is the *prior density* function of θ and x is a sample drawn from the “true” underlying distribution with *sampling density* $p(x|\theta)$ that we model. Thus the posterior distribution for θ takes into account both our prior distribution for θ and the observed data x .

A *conjugate prior family* is a class of densities $p(\theta_i)$ which has the feature that given the sampling density $p(x|\theta)$, the posterior density $p(\theta_i|x)$ also belongs to the same class. The name arises because we say that the prior $p(\theta_i)$ is *conjugate* to the sampling density considered as a *likelihood* function $p(x|\theta)$ for θ given x . The concept of conjugate prior as well as the term was introduced by Raiffa and Schlaifer [1].

After obtaining a posterior distribution for the parameters θ we can compute various quantities of interest such as integrals of the form

$$\int f(y)g(y;\theta)p(\theta|x) dy d\theta \quad (2)$$

where f is some arbitrary function and g is the probability density function describing a related parametric model. In general, because we are not assuming independence between each of the individual parameters, this integral is difficult to compute especially if there are many parameters. This is the situation in which *Markov chain Monte Carlo (MCMC)* (see **Reliability Demonstration; Imprecise Reliability**) simulation is most commonly used.

The distinguishing feature of MCMC is that the random samples of the integrand in equation (1) are *correlated*, whereas in conventional Monte Carlo methods such samples are *statistically independent*. The goal of MCMC methods is to construct an ergodic Markov chain (see **Repair, Inspection, and Replacement Models**) that converges quickly to its stationary distribution which is the required posterior density or some functional thereof such as equation (2).

One can broadly categorize the use of MCMC methods as Bayesian or non-Bayesian. *Non-Bayesian* MCMC methods are used to compute quantities that depend on a distribution from a statistical model that is *nonparametric*. In a *Bayesian* application, we consider a *parametric* model for the problem of interest. We assume some prior distribution on the parameters and try to compute quantities of interest that involve the posterior distributions. This approach remains suitable if the data is sparse, for example, in extreme value applications [2] (see **Statistics for Environmental Toxicity; Extreme Value Theory in Finance; Mathematics of Risk and Reliability: A Select History; Multiattribute Modeling**).

There are many different types of MCMC algorithms. The two most basic and widely used algorithms are the *Metropolis–Hastings algorithm* and the *Gibbs sampler* (see **Bayesian Statistics in Quantitative Risk Assessment**) which will be reviewed subsequently.

Metropolis–Hastings Algorithm

The Metropolis–Hastings algorithm [3–5] has been used extensively in physics but was little known to others until Müller [6] and Tierney [7] expounded its value to statisticians. This algorithm is extremely powerful and versatile and has been included in a list of “top 10 algorithms” [8] and even claimed to be most likely the most powerful algorithm of all time [9].

The Metropolis–Hastings algorithm can draw samples from any *target* probability density π for the uncertain parameters θ requiring only that this density can be calculated at θ . The algorithm makes use of a *proposal density* $q(\theta^t, \zeta)$, which depends on the current state of the chain θ^t to generate each new proposed parameter sample ζ . The proposal ζ is “accepted” as the next state of the chain ($\theta^{t+1} := \zeta$) with *acceptance probability* $\alpha(\theta^t, \zeta)$ and “rejected” otherwise. It is the specification of this probability α that allows us to generate a Markov chain with the desired target stationary density π . The Metropolis–Hastings algorithm can thus be seen as a generalized form of *acceptance/rejection sampling* with values drawn from approximate distributions, which are “corrected” in order that they behave asymptotically as random observations from the target distribution.

The algorithm in step-by-step form is as follows:

1. Given the current position of our Markov chain θ^t , generate a new value ζ from the proposal density q (see below).
2. Compute the *acceptance probability*

$$\alpha(\theta^t, \zeta) := \min \left(1, \frac{\pi(\zeta)q(\zeta, \theta^t)}{\pi(\theta^t)q(\theta^t, \zeta)} \right) \quad (3)$$

where π is the density of the target distribution.

3. With probability $\alpha(\theta^t, \zeta)$, set $\theta^{t+1} := \zeta$, else set $\theta^{t+1} := \theta^t$.
4. Return to step 1.

This algorithm generates a discrete time ergodic Markov chain $(\theta^t)_{t \geq 0}$ with stationary distribution Π corresponding to π , i.e., as $t \rightarrow \infty$

$$P(\theta^t \in B) \rightarrow \Pi(B) \quad (4)$$

for all suitably (Borel) measurable sets $B \in \mathbb{R}^n$.

Some important points to note are given in [5]:

- We need to specify a starting point θ^0 , which may be chosen at random (and often is). Preferably θ^0 should coincide with a mode of the density π .
- We should also specify a *burn-in period* to allow the chain to reach equilibrium. By this we mean that we discard the first n values of the chain in order to reduce the possibility of bias caused by the choice of the starting value θ^0 .
- The *proposal distribution* should be a distribution that is easy to sample from. It is also desirable to

choose its density q to be “close” or “similar” to the target density π , as this will increase the acceptance rate and increase the efficiency of the algorithm.

- We only need to know the *target density function* π up to proportionality – that is, we do not need to know its normalizing constant, since this cancels in the calculation (3) of the *acceptance function* α .

The choice of the burn-in period still remains somewhat of an art, but is currently an active area of research. One can simply use the “eyeballing technique” which merely involves inspecting visual outputs of the chain to see whether or not it has reached equilibrium.

When the proposal density is *symmetric*, i.e. $q(\theta^t, \zeta) = q(\zeta, \theta^t)$ (the original Metropolis algorithm), the computation of the acceptance function α is significantly faster. In this case from equation (3) a proposal ζ is accepted with probability $\alpha = \pi(\zeta)/\pi(\theta^t)$, i.e. its likelihood $\pi(\zeta)$ relative to that of $\pi(\theta^t)$ (as originally suggested by Ulam for acceptance/rejection sampling).

Random Walk Metropolis

If $q(\theta^t, \zeta) := f(|\theta - \zeta|)$ for some density f and norm $|\cdot|$, then this case is called a *random walk chain* (see **Statistical Arbitrage**) because the proposed states are drawn according to the process following $\zeta = \theta^t + \mathbf{v}$, where $\mathbf{v} \sim F$, the distribution corresponding to f . Note that, since this proposal density q is symmetric, the acceptance function is of the simple Metropolis form described above. Common choices for q are the multivariate normal, multivariate t or the uniform distribution on the unit sphere.

If $q(\theta^t, \zeta) := q(\zeta)$, then the candidate observation is drawn *independently* of the current state of the chain. Note, however, that the state of the chain θ^{t+1} at $t + 1$ does depend on the previous state θ^t because the acceptance function $\alpha(\theta^t, \cdot)$ depends on θ^t .

In the random walk chain we only need to specify the *spread* of q , i.e. a maximum for $|\theta - \zeta|$ at a single step. In the independence sampler we need to specify the spread and the location of q .

Choosing the spread of q is also something of an art. If the spread is large, then many of the candidates will be far from the current value. They

will, therefore, have a low probability of being accepted, and the chain may remain stuck at a particular value for many iterations. This can be especially problematic for multimodal distributions; some of its modes may then not be explored properly by the chain. On the other hand, if the spread is small the chain will take longer to traverse the support of the density and low probability regions will be under sampled. The research reported in [10] suggests an optimal acceptance rate of around 0.25 for the random walk chain. In the case of the independence sampler it is important [11] to ensure that the tails of q dominate those of π , otherwise the chain may get stuck in the tails of the target density. This requirement is similar to that in importance sampling.

Multiple-Block Updates

When the number of dimensions is large it can be difficult to choose the proposal density q so that the algorithm converges sufficiently rapidly. In such cases, it is helpful to break up the space into smaller blocks and to construct a Markov chain for each of these smaller blocks [4]. Suppose that we split θ into two blocks (θ_1, θ_2) and let $q_1(\theta_1^t | \theta_2^t, \zeta_1)$ and $q_2(\theta_2^t | \theta_1^t, \zeta_2)$ be the proposal densities for each block. We then break each iteration of the Metropolis–Hastings algorithm into two steps and at each step we update the corresponding block. To update block 1 we use the acceptance function given by

$$\alpha(\theta_1^t | \theta_2^t, \zeta_1) := \min \left(1, \frac{\pi(\zeta_1 | \theta_2^t) q_1(\zeta_1 | \theta_2^t, \theta_1^t)}{\pi(\theta_1^t | \theta_2^t) q_1(\theta_1^t | \theta_2^t, \zeta_1)} \right) \quad (5)$$

and to update block 2 we use

$$\alpha(\theta_2^t | \theta_1^t, \zeta_2) := \min \left(1, \frac{\pi(\zeta_2 | \theta_1^t) q_2(\zeta_2 | \theta_1^t, \theta_2^t)}{\pi(\theta_2^t | \theta_1^t) q_2(\theta_2^t | \theta_1^t, \zeta_2)} \right) \quad (6)$$

If each of the blocks consists of just a single variable, then the resulting algorithm is commonly called the *single-update* Metropolis–Hastings algorithm. Suppose in the single-update algorithm it turns out that each of the marginals of the target distribution $\pi(\theta_i | \theta_{\sim i})$ can be directly sampled from. Then we would naturally choose $q(\theta_i | \theta_{\sim i}) := \pi(\theta_i | \theta_{\sim i})$ since all candidates ζ will then be accepted with probability one. This special case uses the well-known *Gibbs sampler* method [11].

Gibbs Sampler

Gibbs sampling is applicable, in general, when the joint parameter distribution is not known explicitly but the conditional distribution of each parameter, given the others, is known. Let $P(\theta) = P(\theta_1, \dots, \theta_k)$ denote the joint parameter distribution and let $p(\theta_i | \theta_{\sim i})$ denote the conditional density for the i th component θ_i given the other $k - 1$ components, where $\theta_{\sim i} := \{\theta_j : j \neq i\}$ for $i = 1, \dots, k$. Although we do not know how to sample directly from P we do know how to sample directly from each $p(\theta_i | \theta_{\sim i})$. The algorithm begins by picking the arbitrary starting value $\theta^0 = (\theta_1^0, \dots, \theta_k^0)$. It then samples randomly from the conditional densities $p(\theta_i | \theta_{\sim i})$ for $i = 1, \dots, k$ successively as follows:

Sample θ_1^1 from $p(\theta_1 | \theta_2^0, \theta_3^0, \dots, \theta_k^0)$

Sample θ_2^1 from $p(\theta_2 | \theta_1^1, \theta_3^0, \dots, \theta_k^0)$

...

Sample θ_k^1 from $p(\theta_k | \theta_1^1, \theta_2^1, \dots, \theta_{k-1}^1)$

This completes a transition from θ^0 to θ^1 and eventually generates a sample path $\theta^0, \theta^1, \dots, \theta^t, \dots$ of a Markov chain whose stationary distribution is P .

In many cases we can use the Gibbs sampler, which is significantly faster to compute than the more general Metropolis–Hastings algorithm. In order to use Gibbs, however, we must know how to directly sample from the conditional posterior distributions for each parameter, i.e. $p(\theta_i | \theta_{\sim i}, x)$, where x represents the data to time t .

Use of MCMC in Capital Allocation for Operational Risk

Because of the lack of reported data on operational losses (see **Individual Risk Models; Extreme Value Theory in Finance; Simulation in Risk Management**) Bayesian MCMC simulation is well suited for the quantification of operational risk and operational risk capital allocation. In [12], a framework for the evaluation of *extreme* operational losses has been developed, which assumes that market and credit risks may be managed separately, but jointly imposes a *value at risk* (VaR) (see **Equity-Linked Life Insurance; Risk Measures and Economic Capital for (Re)insurers; Credit Scoring via Altman Z-Score**) limit u_{VaR} on these risks.

It is assumed that losses beyond the u_{VaR} level belong to the *operational risk* category. In most

cases, owing to the overlapping of risk types, a detailed analysis of operational loss data is required to support the assumption that the u_{VaR} level approximately equals the *unexpected loss threshold*. This approach to capital allocation for operational risk, which takes into account large but rare operational losses, is naturally based on *extreme value theory* (EVT) [13, 14] and focuses on tail events and modeling the worst-case losses as characterized by loss maxima over regular observation periods.

According to regulatory requirements [15], operational risk capital calculation requires two distributions – a *severity* distribution of loss values (see **Individual Risk Models; Insurance Pricing/Nonlife**) and a *frequency* distribution of loss occurrences. In the approach described here a unified resulting asymptotic model known as the *peaks over threshold* (POT) model [16–18] (see **Extreme Value Theory in Finance; Extreme Values in Reliability**) is applied. It is based on an asymptotic theory of extremes and a point process representation of exceedances over a threshold given to specify the POT model. The following assumption is made.

Given an *i.i.d.* sequence of random losses $X_1, \dots, X_n$ drawn from some distribution we are interested in the distribution of the *excess* $\mathbf{Y} := \mathbf{X} - u$ over the threshold u . The distribution of excesses is given by the conditional distribution function in terms of the tail of the underlying distribution function F as

$$F_u(y) := P(\mathbf{X} - u \leq y | \mathbf{X} > u) = \frac{F(u+y) - F(u)}{1 - F(u)} \quad \text{for } 0 \leq y \leq \infty \quad (7)$$

The limiting distribution $G_{\xi, \beta}(y)$ of excesses as $u \rightarrow \infty$ is known as the *generalized Pareto distribution* (GPD) with *shape* parameter ξ and *scale* parameter β given by

$$G_{\xi, \beta}(y) = \begin{cases} 1 - \left(1 + \xi \frac{y}{\beta}\right)^{-1/\xi} & \xi \neq 0 \\ \text{where } y \in [0, \xi] & \xi \geq 0 \\ \text{or } y \in [0, -\beta/\xi] & \xi < 0 \\ 1 - \exp\left(-\frac{y}{\beta}\right) & \xi = 0 \end{cases} \quad (8)$$

The identification of an appropriate threshold u is again somewhat of an art and requires a data analysis based on a knowledge of EVT [13, 14, 19].

The *capital provision* for operational risk over the unexpected loss threshold u is given in [2] as

$$\lambda_u E(\mathbf{X} - u | \mathbf{X} > u) = \lambda_u \frac{\beta_u + \xi u}{1 - \xi} \quad (9)$$

where $E(\mathbf{X} - u | \mathbf{X} > u) = \frac{\beta_u + \xi u}{1 - \xi}$ is the *expectation* of excesses over the threshold u (which is defined for $\xi \leq 1$ and must be replaced by the *median* for $\xi > 1$), $\beta_u := \sigma + \xi(u - \mu)$ and the exceedances form a Poisson point process with *intensity*

$$\lambda_u := \left(1 + \xi \frac{(u - \mu)}{\sigma}\right)^{-1/\xi} \quad (10)$$

usually measured in days per annum.

The accuracy of our model depends on accurate estimates of the ξ , μ , σ , and β parameters. To address this, hierarchical Bayesian MCMC simulation (see **Bayesian Statistics in Quantitative Risk Assessment**) is used to determine the parameter estimates of interest through intensive computation. The empirical estimation efficiency of this method when back-tested on large data sets is surprisingly good.

Hierarchical Bayesian parameter estimation considers the parameters to be random variables possessing a joint probability density function. The prior density $f_{\theta|\psi}$ of the random parameter vector θ is parametric with a vector of random *hyperparameters* ψ and is conjugate prior to the sampling density $f_{\mathbf{X}|\theta}$ so that the calculated posterior density $f_{\theta|\mathbf{X}_1, \dots, \mathbf{X}_n, \psi} := f_{\theta|\psi+}$ is of the same form with the new hyperparameters $\psi+$ determined by ψ and the observations $X_1, \dots, X_n$. In the hierarchical Bayesian model, the *hyper-hyper parameters* φ are chosen to generate a vague prior due to the lack of a prior distribution for the hyperparameters before excess loss data is seen. Hence, we can decompose the posterior parameter density $f_{\theta|\mathbf{X}, \psi}$ with the observations X and the initial hyper-hyper parameters φ as

$$\begin{aligned} f_{\theta|\mathbf{X}, \psi} &\propto f_{\mathbf{X}|\theta}(X|\theta) f_{\theta|\psi}(\theta|\psi) f_{\psi}(\psi|\varphi) \\ &\propto f_{\mathbf{X}|\theta}(X|\theta) f_{\psi|\theta}(\psi|\theta, \varphi) \\ &\propto f_{\mathbf{X}|\theta}(X|\theta) f_{\psi}(\psi|\varphi+) \end{aligned} \quad (11)$$

Here the Bayesian update of the prior parameter density $f_{\theta} \propto f_{\theta|\psi} f_{\psi}$ is performed in two stages. First by updating the hyper-hyper parameters φ to $\varphi+$ conditional on θ and then evaluating the

corresponding posterior density for this θ given the observations X .

Hierarchical Bayesian MCMC simulation for the parameters is based on the Metropolis–Hasting algorithm described briefly above and in detail in [20]. The idea is that the state of the chain for the parameter vector $\theta := \{\mu_j, \log \sigma_j, \xi_j : j = 1, 2, \dots, J\}$ converges to a stationary distribution which is the Bayesian posterior parameter distribution $f_{\theta|X, \psi}$ given the loss data x and a vector ψ of *hyperparameters* $\{m_\mu, s_\mu^2, m_{\log \sigma}, s_{\log \sigma}^2, m_\xi, s_\xi^2\}$. The hyperparameters are sampled from a conjugate prior *gamma-normal* (GM) distribution and are used to link the parameters $\{\mu_j, \sigma_j, \xi_j : j = 1, 2, \dots, J\}$ of each individual risk [2].

The aim of the model is to estimate the parameters of interest $\{\mu_j, \sigma_j, \xi_j : j = 1, 2, \dots, J\}$ conditional on both the data X and the hyperparameters $\{m_\mu, s_\mu^2, m_{\log \sigma}, s_{\log \sigma}^2, m_\xi, s_\xi^2\}$. The *posterior* distributions of the parameters are normally distributed:

$$\begin{aligned} \mu_j &\sim N(m_\mu, s_\mu^2), \log \sigma_j \sim N(m_{\log \sigma}, s_{\log \sigma}^2) \\ \text{and } \xi_j &\sim N(m_\xi, s_\xi^2) \end{aligned} \quad (12)$$

A schematic summary of the loss data, parameters, and hyperparameters is given in Table 1.

Illustrative Example

The data is assumed to represent the operational losses of a bank attributable to three different business units. The data starts on January 1, 1980 and ends on December 31, 1990. The time span is calculated in years, hence the parameters will also be measured on a yearly basis. The data has been generated from the Danish insurance claims data [19]

(see Figures 1 and 2) by two independent random multiplicative factors to obtain the three sets of loss data summarized in Table 2.

A typical analysis of such data includes time series plots, log histogram plots, sample mean excess plots, QQ plots for extreme value analysis against the GPD, Hill estimate plots of the shape parameter, and plots of the empirical distribution functions. All these tests have been performed for the three data sets to conclude that data are heavy tailed and that the POT model is valid.

Inputs for the MCMC model:

Threshold $u = 30$

Initial parameters:

μ_1	μ_2	μ_3	$\log \sigma_1$	$\log \sigma_2$	$\log \sigma_3$	ξ_1	ξ_2	ξ_3
20	21	22	3	3.2	2.8	0.5	0.4	0.7

The tables below (Tables 3–5) are a summary of the posterior mean estimates of the parameter values β_i and λ_i based on the MCMC posterior distribution mean parameter values.

The plots in Figure 3 below for the results of 2000 simulation loops show that convergence has been reached for the marginal posterior distributions of all parameters for Unit 1 and that the estimates of these parameters are distributed approximately normally. (Those of σ are thus approximately lognormal.) Similar results hold for the other two units.

The capital provision for operational losses is calculated using equation (9). The probability of such losses is given by the choice of threshold u for extreme operational losses. This threshold must be obtained from an analysis of the historical

The number of exceedances above the threshold is 24.

Figure 3 Simulation results of MCMC for 2000 iterations

operational loss data and should agree or exceed the threshold level u_{VaR} of unexpected losses due to market and credit risk. The probability π of crossing the combined market and credit risk threshold u_{VaR} is

chosen according to the usual *VaR* risk management procedures. The level of losses u due to operational risks is exceeded with probability $\rho \leq \pi$, so that $u \geq u_{\text{VaR}}$. The probability of exceeding u depends

on the shape of the tail of the loss distribution but, in general, is very much smaller than π .

Assuming that three types of losses are the bank business unit losses from operational risk over a period of 11 years the bank should hedge its operational risk for these units by putting aside 944.60 units of capital ($1.39 \times 211.75 + 1.30 \times 218.40 + 1.70 \times 213.50$) for any 1-year period (see Tables 3–5).

Although in this illustrative example unexpected losses above the combined VaR level (30 units of capital) occur with probability 2.5% per annum, unexpected operational risk losses will exceed this capital sum with probability less than 0.5%. In practice, lower tail probabilities might be chosen, but similar or higher probability ratios would be obtained.

Note that in this example the loss data for each business unit was generated as independent and the total capital figure takes the resulting diversification effect into account. On actual loss data, the dependencies in the realized data are taken into account by the method, and the diversification effect of the result can be analyzed by estimating each unit separately and adding the individual capital figures (which conservatively treats losses across units as perfectly correlated) [2]. Although the results presented here are based on very large (2167) original sample sizes, the simulation experiments on actual banking data reported in [2] verify the high accuracy of MCMC Bayesian hierarchical methods for exceedance sample sizes as low as 10 and 25, as in this example.

Conclusion

In this chapter, we have introduced MCMC concepts and techniques and showed how to apply them to the estimation of a Bayesian hierarchical model of interdependent extreme operational risks. This model employs the POT model of EVT to generate both *frequency* and *severity* statistics for the extreme operational losses of interdependent business units, which are of interest at the board level of a financial institution. These are obtained respectively in terms of Poisson exceedences of an unexpected loss level for other risks and the GPD.

The model leads to annual business unit capital allocations for unexpected extreme risks that take account of the statistical interdependencies of individual business unit losses.

The concepts discussed in this chapter are illustrated by an artificially created example involving

three business units but actual banking studies are described in [2] and in forthcoming work relating to internally collected operational loss data.

Bayesian Statistics in Quantitative Risk Assessment

Benefits of the Bayesian Approach in Risk Assessment

Bayesian inference has a number of advantages in modern data analysis and modeling, including applications in different forms of risk assessment. This is true in terms of the flexibility and applicability of Bayesian techniques as a result of the development of Markov chain Monte Carlo (MCMC) computational methods. By virtue of the relevance of Bayesian inferences and methods, it also holds to the types of data and problems tackled by modern scientific research, including those encountered in quantitative risk assessment where full expression of uncertainty surrounding assessment parameters or outcomes is desirable [1]. Useful introductory readings include those by Gelman *et al.* [2], Congdon [3], and Carlin and Louis [4], while more advanced theoretical approaches include Gamerman and Lopes [5], Bernardo and Smith [6], and Chen *et al.* [7].

Bayesian methods are being increasingly applied in risk assessment as they allow incorporation of subjective belief (*see Subjective Expected Utility*) or expert opinion in the form of prior probability distributions [8], as well as probabilistic approaches rather than deterministic exposure assessments [9].

Various forms of risk assessment have been tackled from a Bayesian perspective, and examples of Bayesian approaches can be found in journals such as *Environmental Toxicology*, *Journal of Exposure Science and Environmental Epidemiology*, *Human and Ecological Risk Assessment*, and *Stochastic Environmental Research and Risk Assessment*. Environmental risk assessment (*see Environmental Health Risk Assessment*) typically involves evaluating the potential impact of an exogenous hazard (e.g., air pollution or soil contamination, food poisoning, flood, or other natural disaster) on human populations or ecological systems, or one associated with a possible planned intervention (e.g., assessing the ecological impact of major airport or road schemes). Examples of Bayesian perspectives in such areas are included in [10–13].

Another type of assessment involves exceedance analysis, e.g., obtaining the probability that a 100-year storm will take place on any given year or the return period of a certain size event. Flood exceedance probabilities, calculated from peak annual stream or river discharge measurements, are important in determining the risk associated with the construction of buildings on a flood plain and also determining the size of dam structures [14, 15]. Finally, one may mention risk assessment associated with industrial and engineering applications where the issue is the risk of accidents, component wear out, or system failures [16] (*see Systems Reliability*).

Frameworks for risk assessment may include identifying hazards, quantifying risks or exposures, and evaluating adverse health effects under varying or critical exposure levels (including dose–response modeling; *see Dose–Response Analysis*). Risk assessment may involve a comparison of the potential health impacts of various risk-management interventions (to be included in cost-effectiveness estimates) or a prioritization between different risks.

As mentioned earlier, it is important that risk assessment recognizes the uncertainties in any evaluation, costing or prioritization, and a Bayesian approach is adapted to this, especially in more complex hierarchical models. For instance, assessment of a disease–exposure relationship may be complicated when exposure measurements are subject to measurement error – such that a full model should include a component relating unknown “true” exposure to the observed exposure. Bayesian analysis allows for full expression of parameter uncertainty propagated across linked models – see Draper [17], with Manson [18] providing a flood risk application. Hence, interval estimates fully allowing for uncertainty may be wider than under frequentist approaches to the same problem.

Much of the data from ecological, environmental, and health research has a complex structure, involving hierarchical clustering of subjects, crossed classifications of subjects, or repeated measures on subjects. Furthermore, exposures to pollutants or other forms of risk are typically unevenly distributed both temporally and geographically [19]. The Bayesian approach naturally adapts itself to hierarchically or spatiotemporally correlated effects *via* conditionally specified priors, with the first stage specifying the likelihood of the data given unknown randomly distributed cluster effects, the second stage specifying

the density of the population of cluster effects, and the third stage providing priors on the population parameters. Examples are provided by Friesen *et al.* [20] who consider random-effects modeling of job exposures in historical epidemiological studies, and Symanski *et al.* [21] who consider clustering of exposures by worker, job groups, building, and plant in a random-effects model (see **Occupational Risks; Occupational Cohort Studies**).

A further distinctive feature of much quantitative risk assessment is the availability of substantial accumulated knowledge about important unknowns. In health risk assessments, the primary concern is often the risk of various cancers, though reproductive and developmental outcomes also figure importantly; there is often clinical knowledge about exposure–disease mechanisms for such outcomes and such knowledge, possibly discounted, can be summarized in prior distributions that can be used in risk analysis.

In the next section, we review some potential benefits of a Bayesian approach in risk assessment and other applications. This is followed by a review of the principle of updating from prior to posterior and of considerations in selecting priors. Some of the issues involved in MCMC sampling are then discussed, such as alternative algorithms and convergence, followed by a discussion of some of the most common ways of measuring model fit and checking model adequacy. The chapter concludes with illustrative applications using the WINBUGS program.

Conceptual and Computational Advantages

Bayesian inference arguably has a number of more general conceptual advantages. However, in the past, Bayesian analysis was impeded by the complex numerical integrations needed. Recently developed computer intensive sampling methods of estimation have revolutionized the application of Bayesian methods and enhanced its potential in terms of inferences.

The Bayesian learning process involves modifying or updating prior probability statements about the parameters, held before observing the data, to updated or posterior knowledge that combines both prior knowledge and the data at hand. This provides a natural way of learning from data so that beliefs or evidence can be cumulatively updated – this is

not possible in the same way in classical analysis. While pre-MCMC Bayesian analysis often relied on conjugate analysis where prior and posterior densities for θ have the same form [22], the advent of MCMC has considerably widened the potential for realistic statements about prior evidence. For example, accumulated evidence may suggest that environmental risks or residue concentrations are positively skewed rather than normally distributed.

The Bayes' method provides interval estimates on parameters that are more in line with commonsense interpretations: a Bayesian 95% credible interval containing the true parameter with 95% probability, whereas classical interpretation of the 95% confidence interval is as the range of values containing the true parameter in 95% of repeated samples.

Using modern sampling methods, Bayesian methods can be applied to complex random-effects models that are difficult to fit using classical methods, and allow inferences without assumptions of asymptotic normality that underlie classical estimation methods. MCMC methods provide a full density profile of a parameter so that any clear nonnormality is apparent, and permit a range of hypotheses about the parameters to be assessed using the sample information.

Prior to Posterior Updating

Bayesian models are typically concerned with inferences on a parameter set $\theta = (\theta_1, \dots, \theta_d)$ of dimension d , which may include “fixed effect” parameters (such as regression coefficients in a normal errors linear regression), random effects as in multilevel or spatial models, hierarchical parameters, unobserved states (in time series models), or even missing observations [23]. For example in a normal linear regression with p predictors, the unknowns would have the dimension $p + 2$, namely, a constant β_0 , regression coefficients for the predictors $\beta_1, \dots, \beta_p$, and the variance term σ^2 .

Expressing prior subject matter knowledge about parameters is an important aspect of the Bayesian modeling process. Such knowledge is summarized in a set of densities $\{p(\theta_1), p(\theta_2), \dots, p(\theta_d)\}$, which are collectively denoted as $p(\theta)$. The likelihood of the observations may be denoted as $p(y|\theta)$. The updated knowledge about parameters conditional on the prior and the data is then contained in a posterior density $p(\theta|y)$. From Bayes' theorem (see **Bayes' Theorem**

and Updating of Belief), one has

$$p(\theta|y) = \frac{p(y|\theta)p(\theta)}{p(y)} \quad (1)$$

where the denominator on the right side is known as the *marginal likelihood* $p(y)$, and is a normalizing constant to ensure that $p(\theta|y)$ is a proper density (integrates to 1). So, one can express the Bayes' inference process as

$$p(\theta|y) \propto p(y|\theta)p(\theta) \quad (2)$$

since posterior knowledge is a function of the data and prior beliefs. The relative impact of the prior and data on updated beliefs depends on how “informative” the prior is – how precise the density $p(\theta)$ is – and the sample size of the data. A large sample would tend to outweigh even an informative prior. Note that certain priors (e.g., that a regression parameter only take positive values) do have an enduring impact on posterior inferences.

In hierarchical models involving latent data Z (e.g., random effects, missing observations), the joint density has the form $p(y, \theta, Z) = p(y|\theta, Z)p(\theta, Z) = p(y|\theta, Z)p(Z|\theta)p(\theta)$. The posterior density for both Z and θ is

$$p(Z, \theta|y) = \frac{p(y|\theta, Z)p(Z|\theta)p(\theta)}{p(y)} \quad (3)$$

Choice of Prior Density

Choice of an appropriate prior density, whether in mathematical terms or in terms of being subjectively justified by the application is an important issue in the Bayesian approach – which tends to militate against menu driven “off the shelf” application. There are also mathematical reasons to prefer some sorts of prior to others, though the advent of MCMC methods and a range of rejection sampling methods has reduced the need for restricting models to conjugate priors. Thus a β density for a binomial probability is conjugate with a binomial likelihood since the posterior has the same (β) density form as the prior. There may be questions of sensitivity to the choice of prior especially in certain forms of model – examples are the priors used in hierarchical models and in discrete mixture models.

It may be possible to base the prior density for θ on cumulative evidence *via* meta-analysis of existing studies (*see Meta-Analysis in Nonclinical Risk*

Assessment), or *via* elicitation techniques aimed at developing informative priors. This is well established in assessment of engineering risk and reliability, where systematic elicitation approaches such as maximum-entropy priors are used [24, 25]. Simple approximations include the histogram method, which divides the domain of θ into a set of bins and elicits prior probabilities that θ is located in each bin; then $p(\theta)$ may be represented as a discrete prior or converted to a smooth density. Prior elicitation may be aided if a prior is reparameterized in the form of a mean and variance; for example, β priors $\text{Beta}(a, b)$ for probabilities can be expressed as $\text{Beta}(m\tau, (1-m)\tau)$ where m is an estimate of the mean probability and τ is the estimated precision (degree of confidence) of that prior mean.

If a set of existing studies is available providing evidence on the likely density of a parameter, these may be used in the form of preliminary meta-analysis to set up an informative prior for the current study. However, there may be limits to the applicability of existing studies to the current data, and so pooled information from previous studies may be downweighted. For example, the precision of the pooled estimate from previous studies may be scaled downwards, with the scale possibly an extra unknown. When a maximum-likelihood analysis is simple to apply, one option is to downweight the variance–covariance matrix of the maximum likelihood estimate (MLE) [26]. More comprehensive ways of downweighting historical/prior evidence, such as power prior models, have been proposed [27, 28].

Especially in hierarchical models, the form of the second stage prior $p(Z|\theta)$ amounts to a hypothesis about the nature of the random effects. Thus a hierarchical model for small area mortality models may include spatially structured random effects, exchangeable random effects with no spatial pattern, or both, as under the convolution prior of Besag *et al.* [29]. A prior specifying the errors as spatially correlated is likely to be a working model assumption, rather than a true cumulation of knowledge, and one may have several models being compared, with different forms assumed for $p(Z|\theta)$.

In many situations, existing knowledge may be difficult to summarize or elicit in the form of an “informative prior” and to express prior ignorance one may use “default” or “noninformative” priors, and this is generally not problematic for fixed effects (such as linear regression coefficients). Since the

classical maximum-likelihood estimate is obtained without considering priors on the parameters, a possible heuristic is that a noninformative prior leads to a Bayesian posterior estimate close to the maximum-likelihood estimate. It might appear that a maximum-likelihood analysis would, therefore, necessarily be approximated by flat or improper priors, such that a parameter is uniformly distributed between $-\infty$ and $+\infty$, or between 0 and $+\infty$ for a positive parameter. However, such priors may actually be unexpectedly informative about different parameter values [30, 31]. An intermediate option might be a diffuse but proper prior such as a uniform prior with a large but known range or a normal prior with very large variance.

For variance parameters, choice of a noninformative prior is more problematic as improper priors may induce improper posteriors that prevent MCMC convergence, as in a normal hierarchical model with subjects j nested in clusters i ,

$$y_{ij} \sim N(\theta_i, \sigma^2) \quad (4)$$

$$\theta_i \sim N(\mu, \tau^2) \quad (5)$$

The prior $p(\mu, \tau) = 1/\tau$ results in a improper posterior [32]. Flat priors on any particular scale will not be flat on another scale (examples include flat priors on σ (confined to positive values), σ^2 , $\log(\sigma)$, or $\log(\sigma^2)$). Just proper priors (e.g., a γ on $1/\sigma^2$ with small scale and shape parameters) do not necessarily avoid these problems and in fact may favor particular values despite being supposedly only weakly informative. Such priors may cause identifiability problems and impede MCMC convergence [33]. Choice of suitable priors for variances in hierarchical models is an active research area [34–36].

Analytically based rules for deriving noninformative priors include reference priors [37] and Jeffreys' prior

$$p(\theta) \propto |I(\theta)|^{0.5} \quad (6)$$

where $I(\theta)$ is the information matrix, namely, $I(\theta) = -E \left\{ \frac{\partial^2 \ell(\theta)}{\partial \ell(\theta_i) \partial \ell(\theta_j)} \right\}$ where $l(\theta) = \log(L(\theta|y))$ is the log-likelihood. Unlike uniform priors, Jeffreys prior is invariant under transformation of scale.

To assess sensitivity to prior assumptions, the analysis may be repeated for a limited range of alternative priors [38], possibly following the principle of Spiegelhalter *et al.* [39] in providing a range of viewpoints; for example, a prior on a treatment effect in

a clinical trial might be neutral, sceptical, or enthusiastic. Formal approaches to prior robustness may be based on mixture or “contamination” priors. For instance, one might assume a two group mixture with larger probability $1 - q$ on the “main” prior $p_1(\theta)$, and a smaller probability such as $q = 0.2$ on a contaminating density $p_2(\theta)$, which may be any density [40]. One might consider the contaminating prior to be a flat reference prior, or one allowing for shifts in the main prior's assumed parameter values [41, 42].

MCMC Sampling and Inferences from Posterior Densities

Bayesian inference has become intimately linked to sampling-based estimation methods that focus on obtaining the entire posterior density of a parameter. A variety of adaptations of Monte Carlo methods have been proposed to sample from posterior densities. Standard Monte Carlo methods generate independent simulations $u^{(1)}, u^{(2)}, \dots, u^{(T)}$ from a target density $\pi(u)$, so that $E_\pi[g(u)] = \int g(u)\pi(u) du$ is estimated as

$$\bar{g} = \frac{1}{T} \sum_{t=1}^T g(u^{(t)}) \quad (7)$$

and $\bar{g}$ tends to $E_\pi[g(u)]$ as $T \rightarrow \infty$. By contrast, independent sampling from the posterior density $\pi(\theta) = p(\theta|y)$ is not usually feasible but dependent samples $\theta^{(t)}$ can be used provided the sampling satisfactorily covers the support of $p(\theta|y)$ [43]. So MCMC methods generate dependent draws *via* Markov chains defined by the assumption

$$p(\theta^{(t)}|\theta^{(1)}, \dots, \theta^{(t-1)}) = p(\theta^{(t)}|\theta^{(t-1)}) \quad (8)$$

so that only the preceding state is relevant to the future state. Sampling from such a Markov chain converges to the stationary distribution required, $\pi(\theta)$, if additional requirements (irreducibility, aperiodicity, and positive recurrence) on the chain are satisfied.

There is no limit to the number of samples T of θ that may be taken from a posterior density $p(\theta|y)$. Such sampling generates estimates of density characteristics (moments, quantiles, 95% credible intervals), and can be used to provide probabilities on hypotheses relating to the parameters [44]. For example, the 95% credible interval may be estimated using the 0.025 and 0.975 quantiles of the sampled

output $\{\theta_k^{(t)}, t = B + 1, \dots, T\}$, where B is a prior sequence of iterations to ensure convergence.

Monte Carlo posterior summaries typically include posterior means and variances of the parameters, obtainable as moment estimates from the MCMC output. This is equivalent to estimating the integrals

$$E(\theta_k|y) = \int \theta_k p(\theta|y) d\theta \quad (9)$$

$$\begin{aligned} \text{Var}(\theta_k|y) &= \int \theta_k^2 p(\theta|y) d\theta - [E(\theta_k|y)]^2 \\ &= E(\theta_k^2|y) - [E(\theta_k|y)]^2 \end{aligned} \quad (10)$$

One may also use the MCMC output to obtain posterior means, variances, and credible intervals for functions $\Delta = \Delta(\theta)$ of the parameters [45]. These are estimates of the integrals

$$E[\Delta(\theta)|y] = \int \Delta(\theta) p(\theta|y) d\theta \quad (11)$$

$$\begin{aligned} \text{Var}[\Delta(\theta)|y] &= \int \Delta^2 p(\theta|y) d\theta - [E(\Delta|y)]^2 \\ &= E(\Delta^2|y) - [E(\Delta|y)]^2 \end{aligned} \quad (12)$$

For $\Delta(\theta)$ its posterior mean is obtained by calculating $\Delta^{(t)}$ at every MCMC iteration from the sampled values $\theta^{(t)}$. The theoretical justification for such estimates is provided by the MCMC version of the law of large numbers [46], namely, that

$$\sum_{t=1}^T \Delta(\theta^{(t)})/T \longrightarrow E_{\pi}[\Delta(\theta)] \quad (13)$$

provided that the expectation of $\Delta(\theta)$ under $\pi(\theta) = p(\theta|y)$, denoted $E_{\pi}[\Delta(\theta)]$, exists.

Posterior probability estimates may also be made using the samples from an MCMC run. These might relate to the probability that θ_k exceeds a threshold b , and provide an estimate of the integral $\Pr(\theta_k > b|y) = \int_b^{\infty} p(\theta_k|y) d\theta_k$. This would be estimated by the proportion of iterations where $\theta_k^{(t)}$ exceeded b , namely,

$$\hat{Pr}(\theta_k > b|y) = \sum_{t=1}^T 1(\theta_k^{(t)} > b)/T \quad (14)$$

where $1(A)$ is an indicator function that takes the value 1 when A is true, or 0 otherwise. Thus in a disease mapping application, one might wish to

obtain the probability that an area's smoothed relative mortality risk θ_k exceeds one, and so count iterations where this condition holds.

Summarizing Inferences from a Bayesian Analysis

Posterior summaries of parameters or related theoretical quantities typically include posterior means and variances of individual parameters, as well as selected percentiles, e.g., the 5th and 95th or the 2.5th and 97.5th. It is useful to present the posterior median as well as the posterior mean to provide at least an informal check on possible asymmetry in the posterior density of a parameter.

From the percentile tail points, the associated equal-tail credible interval for a parameter can be obtained (e.g., the 90% credible interval is obtained if the summary includes the 5th and 95th percentiles from the MCMC sampling output). Another form of credible interval is the $100(1 - \alpha)\%$ highest probability density (HPD) interval, defined such that the density for every point inside the interval exceeds that for every point outside the interval, and also defined to be the shortest possible $100(1 - \alpha)\%$ credible interval.

An overall depiction of the marginal posterior density of an individual parameter may be provided by a histogram or kernel smoothing density estimate [47], based on the full set of posterior samples for individual parameters from the MCMC run subsequent to convergence. A bivariate kernel density may be estimated to summarize the joint posterior densities of two parameters. Such plots will demonstrate whether posterior normality is present or instead features such as skewness or multiple modes are present. As an example of a clearly nonnormal posterior, Gelfand *et al.* [48] present a kernel density estimate for a variance ratio.

Summary presentations or graphical checks on collections of parameters (e.g., a set of random effects) may also be relevant – for example, school effects in a multilevel analysis of exam results. One may use relevant plots (e.g., $Q-Q$ or histogram plots) to assess assumptions of normality typically made in the priors about such effects; this would involve plotting the posterior means or medians of all the effects [49].

The remaining practical questions include establishing an MCMC sampling scheme (see section titled “MCMC Sampling Algorithms”) and that convergence to a steady state has been obtained for practical

purposes (see section titled “Assessing MCMC Convergence”). The sampling output can also be used to provide model fit and model checking criteria (see section titled “Model Fit and Predictions from the Model”). For example, one may sample predictions from the model in the form of replicate data $y_{\text{new}}^{(t)}$ and using these one can check whether a model’s predictions are consistent with the observed data. Predictive replicates are obtained by sampling $\theta^{(t)}$ and then sampling y_{new} from the likelihood model $p(y_{\text{new}}|\theta^{(t)})$.

MCMC Sampling Algorithms

The Metropolis–Hastings algorithm (M–H algorithm) is the prototype for MCMC schemes that simulate a Markov chain $\theta^{(t)}$ for a d -dimensional parameter θ , with $p(\theta|y)$ as the stationary distribution. Following Hastings [50], candidate values θ^* are sampled only according to the improvement they make in $p(\theta|y)$, and if they satisfy a comparison (the Hastings correction) involving a candidate generating density $g(\theta^*|\theta^{(t)})$. This density should ideally be a close approximation for $p(\theta|y)$ but as in the selection of an importance distribution in importance sampling, g should have fatter tails than $p(\theta|y)$ for the algorithm to be efficient.

The M–H algorithm produces a Markov chain that is reversible with respect to $p(\theta|y)$, and so has $p(\theta|y)$ as its stationary distribution [51]. Specifically, the chain is updated from the current value $\theta^{(t)}$ to a potential new value θ^* with probability

$$\alpha(\theta^*|\theta^{(t)}) = \min \left(1, \frac{p(\theta^*|y)g(\theta^{(t)}|\theta^*)}{p(\theta^{(t)}|y)g(\theta^*|\theta^{(t)})} \right) \quad (15)$$

where $g(\theta^*|\theta^{(t)})$ is the ordinate of g for the candidate value, and $g(\theta^{(t)}|\theta^*)$ is the density associated with moving back from θ^* to the current value. If the proposed new value θ^* is accepted, then $\theta^{(t+1)} = \theta^*$; but if it is rejected, the next state is the same as the current state, i.e., $\theta^{(t+1)} = \theta^{(t)}$. An equivalent way of stating the mechanism is

$$\begin{aligned} \theta^{(t+1)} &= \theta^* & \text{if } u \leq \frac{p(\theta^*|y)g(\theta^{(t)}|\theta^*)}{p(\theta^{(t)}|y)g(\theta^*|\theta^{(t)})} \\ \theta^{(t+1)} &= \theta^{(t)} & \text{otherwise} \end{aligned} \quad (16)$$

where u is a draw from a $U(0,1)$ density [52].

The M–H scheme, therefore, has a transition kernel that allows for the possibility of not moving, namely,

$$\begin{aligned} K(\theta^{(t)}, \theta^{(t+1)}) &= g(\theta^{(t+1)}|\theta^{(t)}) \alpha(\theta^{(t+1)}|\theta^{(t)}) + 1(\theta^{(t+1)} = \theta^{(t)}) \\ &\quad \times \int \left[1 - \int \alpha(u|\theta^{(t)}) \right] \times g(u|\theta^{(t)}) du \end{aligned} \quad (17)$$

The target density $p(\theta|y)$ appears in the form of a ratio so it is not necessary to know any normalizing constants, and from equation (2), one can use the scheme

$$\alpha(\theta^*|\theta^{(t)}) = \min \left(1, \frac{p(y|\theta^*)p(\theta^*)g(\theta^{(t)}|\theta^*)}{p(y|\theta^{(t)})p(\theta^{(t)})g(\theta^*|\theta^{(t)})} \right) \quad (18)$$

involving likelihood values $p(y|\theta)$ and ordinates of prior densities $p(\theta)$.

For symmetric proposal densities, with $g(\theta^*|\theta^{(t)}) = g(\theta^{(t)}|\theta^*)$, such as a normal centered at $\theta^{(t)}$, one obtains the simpler Metropolis update scheme [53], whereby

$$\alpha(\theta^*|\theta^{(t)}) = \min \left[1, \frac{p(\theta^*|y)}{p(\theta^{(t)}|y)} \right] \quad (19)$$

Another option is independence sampling, when $g(\theta^*|\theta^{(t)})$ is independent of the current value $\theta^{(t)}$, that is $g(\theta^*|\theta^{(t)}) = g(\theta^*)$. If the proposal density has the form $g(\theta^*|\theta^{(t)}) = g(\theta^{(t)} - \theta^*)$, then a random walk Metropolis scheme is obtained. For example, if $d = 1$, then a univariate normal random walk takes samples $W^{(t)} \sim N(0, 1)$ and a proposal $\theta^* = \theta^{(t)} + \sigma W^{(t)}$, where σ determines the size of the jump (and the acceptance rate). A uniform random walk samples $U^{(t)} \sim U(-1, 1)$ and scales this to form a proposal $\theta^* = \theta^{(t)} + \kappa U^{(t)}$.

The rate at which proposals generated by g are accepted under equations (18) or (19) depends on how close θ^* is to $\theta^{(t)}$, how well the proposal density matches the shape of the target density $p(\theta|y)$, and the variance of the proposal density. For a normal proposal density $g = N(\theta, \Sigma)$, a higher acceptance rate is obtained by reducing the diagonal elements in Σ , but then the posterior density will take longer to explore. A high acceptance rate is not necessarily desirable as autocorrelation in sampled values will be high since the chain is moving in a restricted

portion of the posterior density. A low acceptance rate has the same problem, since the chain is getting locked at particular values. One possibility is to use a variance or dispersion matrix estimate V from a maximum-likelihood analysis, and scale it by a constant $c > 1$, so that the proposal density variance is $\Sigma = cV$ [54]. Performance also tends to be improved if parameters are transformed to the full range of positive and negative values $(-\infty, \infty)$, thus lessening the difficulty of sampling from skewed posterior densities.

In problems where d is large, θ is typically divided into D blocks or components $\theta = (\theta_1, \dots, \theta_D)$, and componentwise updating is applied. Let $\theta_{[j]} = (\theta_1, \theta_2, \dots, \theta_{j-1}, \theta_{j+1}, \dots, \theta_D)$ denote components apart from θ_j , and $\theta_j^{(t)}$ be the current value of θ_j . Suppose that at step j of iteration $t + 1$ the preceding $j - 1$ parameter blocks have already been updated via M-H algorithms, while $\theta_j, \theta_{j+1}, \dots, \theta_D$ are still to be updated. Let the partially updated form of $\theta_{[j]}$ be denoted

$$\theta_{[j]}^{(t,t+1)} = (\theta_1^{(t+1)}, \theta_2^{(t+1)}, \dots, \theta_{j-1}^{(t+1)}, \theta_{j+1}^{(t)}, \dots, \theta_D^{(t)}) \quad (20)$$

The candidate θ_j^* for replacing $\theta_j^{(t)}$ is generated from the j th proposal density, denoted $g(\theta_j^* | \theta_j^{(t)}, \theta_{[j]}^{(t,t+1)})$. Now acceptance of a candidate value involves assessing whether there is improvement or not in the full conditional densities $p(\theta_j^{(t)} | y, \theta_{[j]}^{(t,t+1)})$ that specify the density of θ_j conditional on other parameters $\theta_{[j]}$. The candidate value θ_j^* is accepted with probability

$$\begin{aligned} & \alpha(\theta_j^* | \theta_j^{(t)}, \theta_{[j]}^{(t,t+1)}) \\ &= \min \left[1, \frac{p(\theta_j^* | \theta_{[j]}^{(t,t+1)}, y) g(\theta_j^{(t)} | \theta_j^*, \theta_{[j]}^{(t,t+1)})}{p(\theta_j^{(t)} | \theta_{[j]}^{(t,t+1)}, y) g(\theta_j^* | \theta_j^{(t)}, \theta_{[j]}^{(t,t+1)})} \right] \end{aligned} \quad (21)$$

Gibbs Sampling

The Gibbs sampler [55–57] is a particular componentwise algorithm in which the candidate density $g(\theta^* | \theta)$ for values θ_j^* to update $\theta_j^{(t)}$ equals the full conditional $p(\theta_j^* | \theta_{[j]})$ so that proposals are accepted with probability 1. Gibbs sampling updates involve

successive parameter updating, which when completed forms the transition from $\theta^{(t)}$ to $\theta^{(t+1)}$:

$$\theta_1^{(t+1)} \sim f_1(\theta_1 | \theta_2^{(t)}, \theta_3^{(t)}, \dots, \theta_D^{(t)}) \quad (22)$$

$$\theta_2^{(t+1)} \sim f_2(\theta_2 | \theta_1^{(t+1)}, \theta_3^{(t)}, \dots, \theta_D^{(t)}) \quad (23)$$

$$\theta_D^{(t+1)} \sim f_D(\theta_D | \theta_1^{(t+1)}, \theta_3^{(t+1)}, \dots, \theta_{D-1}^{(t+1)}) \quad (24)$$

Full conditional densities can be obtained by abstracting out from the full posterior density (proportional to likelihood times prior), those elements in the likelihood or prior that include θ_j and treating other components as constants [58]. Ideally, these are standard densities (e.g., gamma, normal) that are easy to simulate from, but nonstandard conditional densities can be sampled using adaptive rejection sampling [59] or the ratio method [60].

Assessing MCMC Convergence

There is no guarantee that sampling from an MCMC algorithm will converge to the posterior distribution, despite obtaining a high number of iterations. Slow convergence will be seen in trace plots that wander or exhibit short-term trends, rather than fluctuating rapidly around a stable mean. Failure to converge is typically evident in a subset of the model parameters; for example, fixed regression effects in a general linear mixed model may show convergence while the parameters relating to the random components may not. Often, measures of overall fit (e.g., model deviance) converge while certain component parameters do not.

Problems of convergence in MCMC sampling may reflect problems in model identifiability: either formal nonidentification as in multiple random-effects models or poor empirical identifiability due to “overfitting”, namely, fitting an overly complex model to a small sample. Choice of diffuse priors tends to increase the chance that models are poorly identified, especially in complex hierarchical models or small samples [61]. Elicitation of more informative priors or application of parameter constraints may assist identification and convergence.

Another source of poor convergence is suboptimal parameterization or data form, and so improved convergence will be obtained under alternative parameterization. For example, convergence is

improved by centering independent variables in regression applications [62]. Similarly, convergence in random-effects models may be lessened by a centered hierarchical prior [63]. Consider two way nested data, with $j = 1, \dots, m$ repetitions over subjects $i = 1, \dots, n$

$$y_{ij} = \mu + \alpha_i + u_{ij} \quad (25)$$

with $\alpha_i \sim N(0, \sigma_\alpha^2)$ and $u_{ij} \sim N(0, \sigma_u^2)$. The centered version has $y_{ij} \sim N(\kappa_i, \sigma_u^2)$ and $\kappa_i \sim N(\mu, \sigma_\alpha^2)$. For three way nested data, the standard model form

$$y_{ijk} = \mu + \alpha_i + \beta_{ij} + u_{ijk} \quad (26)$$

with $\alpha_i \sim N(0, \sigma_\alpha^2)$ and $\beta_{ij} \sim N(0, \sigma_\beta^2)$, whereas the centered version is $y_{ijk} \sim N(\zeta_{ij}, \sigma_u^2)$, $\zeta_{ij} \sim N(\kappa_i, \sigma_\beta^2)$, and $\kappa_i \sim N(\mu, \sigma_\alpha^2)$. Papaspiliopoulos *et al.* [64] compare the effects of centered and noncentered hierarchical model parameterizations on convergence in MCMC sampling.

Many practitioners prefer to use two or more parallel chains with diverse starting values to ensure full coverage of the sample space of the parameters [65]. Running multiple chains often assists in diagnosing poor identifiability of models. This is illustrated most clearly when identifiability constraints are missing from a model, such as in discrete mixture models that are subject to “label switching” during MCMC updating [66]. Single runs may be adequate for straightforward problems, or as a preliminary to obtain inputs to multiple chains. Convergence for multiple chains may be assessed using Gelman–Rubin scale reduction factors (often referred to simply as *G–R statistics* or *G–R factors*) that measure the convergence of the between chain variance in the sampled parameter values to the variance of all the chains combined. The ratio goes to 1 if all chains are sampling identical distributions. Parameter samples from poorly identified models will show wide divergence in the sample paths between different chains and variability of sampled parameter values between chains will considerably exceed the variability within any one chain. To measure variability of samples $\theta_j^{(t)}$ within the j th chain ($j = 1, \dots, J$) over T iterations after a burn-in of B iterations, define

$$w_j = \sum_{t=B+1}^{B+T} \frac{(\theta_j^{(t)} - \bar{\theta}_j)^2}{(T-1)} \quad (27)$$

with variability within chains V_w then defined as the average of the w_j .

Ideally, the burn-in period is a short initial set of samples where the effect of the initial parameter values tails off; during the burn-in phase, trace plots of parameters will show clear monotonic trends as they reach the region of the posterior.

Between chain variance is measured by

$$V_B = \frac{T}{J-1} \sum_{j=1}^J (\bar{\theta}_j - \bar{\theta})^2 \quad (28)$$

where $\bar{\theta}$ is the average of the $\bar{\theta}_j$. The potential scale reduction factor compares a pooled estimator of $\text{Var}(\theta)$, given by $V_P = V_B/T + TV_W/(T-1)$ with the within sample estimate V_W . Specifically, the potential scale reduction factor (PSRF) is $(V_P/V_W)^{0.5}$ with values under 1.2 indicating convergence.

Another multiple chain convergence statistic is due to Brooks and Gelman [67] and known as the *Brooks–Gelman–Rubin (BGR) statistic*. This is a ratio of parameter interval lengths, where for chain j the length of the $100(1-\alpha)\%$ interval for a parameter is the gap between 0.5α and $(1-0.5\alpha)$ points from T simulated values $\theta^{(t)}$. This provides J within-chain interval lengths, with mean I_W . For the pooled output of TJ samples, the same $100(1-\alpha)\%$ interval I_P is also obtained. Then the ratio I_P/I_W should converge to 1 if there is convergent mixing over different chains. Brooks and Gelman also propose a multivariate version of the original G–R scale reduction factor.

Since parameter samples obtained by MCMC methods are dependent, there will be correlations at lags 1, 5, etc., the size of which depends (*inter alia*) on the form of parameterization, the complexity of the model, and the form of MCMC sampling used (e.g., block or univariate sampling). Nonvanishing autocorrelations at high lags mean that less information about the posterior distribution is provided by each iterate and a higher sample size T is necessary to cover the parameter space. Analysis of autocorrelation in sequences of MCMC samples amounts to an application of time series methods, in regard to issues such as assessing stationarity in an autocorrelated sequence. Autocorrelation at lags 1, 2, and so on may be assessed from the full set of sampled values $\theta^{(t)}, \theta^{(t+1)}, \theta^{(t+2)}, \dots$, or from subsamples K steps apart $\theta^{(t)}, \theta^{(t+K)}, \theta^{(t+2K)}, \dots$, etc. If the chains are mixing satisfactorily, then the autocorrelations in the one step apart iterates $\theta^{(t)}$ will fade to zero as the lag increases (e.g., at lag 10 or 20).

Model Fit and Predictions from the Model

Methods to assess models must be able to choose among different models, though if a few models are closely competing, an alternative strategy is to average over models. However, choosing the best fitting model is not an end to model criticism since even the best model may not adequately reproduce the data.

Consider model choice first. Let m be a multinomial model index, with m taking values between 0 and K . Formal Bayes' model choice is based on prior model probabilities $P(m = k)$ and marginal likelihoods $P(y|m = k)$, which are the normalizing constants in the Bayes' formula,

$$P(\theta_k|y, m = k) = \frac{P(y|\theta_k, m = k)P(\theta_k|m = k)}{P(y|m = k)} \quad (29)$$

The marginal likelihood can be written as

$$P(y|m = k) = \frac{P(y|\theta_k, m = k)\pi(\theta_k|m = k)}{P(\theta_k|y, m = k)} \quad (30)$$

or following a log transform as

$$\begin{aligned} \log[P(y|m = k)] &= \log[P(y|\theta_k, m = k)] \\ &\quad + \log[P(\theta_k|m = k)] \\ &\quad - \log[P(\theta_k|y, m = k)] \end{aligned} \quad (31)$$

The term $\log[P(\theta_k|m = k)] - \log[P(\theta_k|y, m = k)]$ is a penalty favoring parsimonious models, whereas a more complex model virtually always leads to a higher log-likelihood $\log[P(y|\theta_k, m = k)]$. The marginal likelihood is thus the probability of the data y given a model, and is obtained by averaging over the priors assigned to the parameters in that model, since

$$P(y|m = k) = \int P(y|\theta_k, m = k)\pi(\theta_k|m = k) d\theta_k \quad (32)$$

Suppose choice is confined to two possible models, $m = 0$ and 1. One may fit them separately and consider their relative fit in terms of summary statistics, such as the marginal likelihood. Alternatively, using model search techniques such as reversible jump MCMC [62], one may search over models k as well as over parameter values $\{\theta_k|m = k\}$. The best

model is chosen on the basis of posterior probabilities on each model. Under the first scenario, such probabilities involve the ratio of marginal likelihoods $P(y|m = 1)/P(y|m = 0)$, also termed the *Bayes' factor* and denoted B_{10} , and the ratio of the prior probabilities, $Q_1 = P(m = 1)/P(m = 0)$. The posterior probability of a model is obtained from its prior probability and the marginal likelihood *via* the formula $P(m = k|y) = P(m = k)P(y|m = k)/P(y)$. It follows that

$$\begin{aligned} P(m = 1|y)/P(m = 0|y) &= P(y|m = 1)P(m = 1)/[P(y|m = 0)P(m = 0)], \\ &= B_{10}[P(m = 1)/P(m = 0)] \end{aligned} \quad (33)$$

namely, that the posterior odds on model 1 equal the Bayes' factor times the prior odds on model 1. Under the second scenario, the proportion of samples when model k is chosen is equal to $P(m = k|y)$ when prior model probabilities are equal. There is no necessary constraint in these model comparisons that models 0 and 1 are nested with respect to one another – an assumption often necessarily made in classical tests of goodness of model fit.

If the posterior model probability of a particular model among $K + 1$ options is above some critical threshold (e.g., $P(m = k|y) > 0.01$), then model averaging may be carried out [68]. The average density of a parameter function Δ is obtained as

$$P(\Delta|y) = \sum_{k=0}^{K} P(\Delta_k|m = k, y)P(m = k|y) \quad (34)$$

Model averaging can be done in other ways, such as when regression variable selection is used, or when time series switching models are applied [69].

The marginal likelihood can be difficult to obtain in complex models and other “informal” techniques are often used. A widely used approach is analogous to the Akaike Information Criterion (AIC) in classical statistics [70], namely, the deviance information criterion (DIC) of Spiegelhalter *et al.* [71]. In developing this criterion, Spiegelhalter *et al.* propose an estimate for the total number of effective parameters or model dimension, denoted d_e , generally less than the nominal number of parameters in hierarchical random-effects models. Let $L^{(t)} = \log[P(y|\theta^{(t)})]$ denote the log-likelihood obtained at the t th iteration in an MCMC sequence, with $D^{(t)} = -2L^{(t)}$

then being the deviance at that iteration. Then $d_e = E(D|y, \theta) - D(\bar{\theta}|y)$, where $E(D|y, \theta)$ is estimated by the mean $\bar{D}$ of the sampled deviances $D^{(t)}$, and $D(\bar{\theta}|y)$ is the deviance at the posterior mean $\bar{\theta}$ of the parameters. The DIC is then

$$D(\bar{\theta}|y) + 2d_e \quad (35)$$

with the model having the lowest DIC being preferred. Effective parameter estimates in practice include aspects of a model such as the precision of its parameters and predictions.

While a DIC or posterior model probability might favor one model over another it still remains a possibility that none of the models being considered reproduces the data effectively. Model checking involves assessing whether predictions from the model reproduce the main features of the data and particular unusual features of the data as well such as skewness or bimodality. The most widely applied Bayesian model checking procedures are based on replicate data y_{rep} sampled from the model. These also constitute a model prediction under the Bayesian approach and often figure centrally in uncertainty statements in risk assessment applications; examples include the prediction of risk of infectious disease over a region using risk mapping methods based on existing disease point patterns [72].

In the Bayesian method, the information about θ is contained in the posterior density $p(\theta|y)$ and so prediction is correspondingly based on averaging predictions $p(y_{\text{rep}}|y, \theta)$ over this posterior density. Generally $p(y_{\text{rep}}|y, \theta) = p(y_{\text{rep}}|\theta)$, namely, that predictions are independent of the observations given θ , so that the posterior predictive density is obtained as

$$p(y_{\text{rep}}|y) = \int p(y_{\text{rep}}|\theta)p(\theta|y) d\theta \quad (36)$$

A model checking procedure based on the posterior predictive density $p(y_{\text{rep}}|y)$, involves a discrepancy measure $D(y_{\text{obs}}; \theta)$, such as the deviance or χ^2 [73]. The realized value of the discrepancy $D(y_{\text{obs}}; \theta)$ is located within its reference distribution by a tail probability analogous to a classical p value:

$$p_b(y_{\text{obs}}) = P_R[D(y_{\text{rep}}; \theta) > D(y_{\text{obs}}; \theta) | y_{\text{obs}}] \quad (37)$$

In practice, this involves calculating $D(y_{\text{rep}}^{(t)}, \theta^{(t)})$ and $D(y_{\text{obs}}, \theta^{(t)})$ in an MCMC run of length T and then calculating the proportion of samples for

which $D(y_{\text{rep}}^{(t)}, \theta^{(t)})$ exceeds $D(y_{\text{obs}}, \theta^{(t)})$. Systematic differences in distributional characteristics (e.g., in percents of extreme values or in ratios of variances to means) between replicate and actual data indicate possible limitations in the model(s). Specifically, values of p_b around 0.5 indicate a model consistent with the actual data, whereas extreme values (close to 0 or 1) suggest inconsistencies between model predictions and actual data.

Another model checking procedure based on replicate data is suggested by Gelfand [74] and involves checking for all sample cases $i = 1, \dots, n$ whether observed y are within 95% intervals of y_{rep} . This procedure may also assist in pointing to possible overfitting, e.g., if all (i.e., 100%) of the observed y are within 95% intervals of y_{rep} .

Illustrative Applications in WINBUGS

We consider two worked examples where principles of risk assessment are involved. The analysis uses the freeware WINBUGS package (now being developed under the acronym OPENBUGS) which has a syntax based on the S+ and R packages. Discussion on how to use WINBUGS appears in [75, 76], and [77, Appendix B].

Ground Ozone Exceedances

The first application involves an air quality time series (*see Air Pollution Risk*). Elevated concentrations of ground level ozone are harmful to human health and ecosystems. In humans, concentrations of $200 \mu\text{g m}^{-3}$ (over 8 h) cause irritation to the eyes and nose and very high levels (over $1000 \mu\text{g m}^{-3}$) may inhibit lung function through inflammatory response. Ground level (tropospheric) ozone also may contribute to acid rain formation and damage some man-made materials such as elastomers and fabrics.

In the United Kingdom, an Air Quality Strategy objective has been set for ground level ozone, namely, that the maximum daily concentration (measured via 8-h running means through the day) should not exceed $100 \mu\text{g m}^{-3}$ for more than 10 days yr^{-1} . Hence an annual record for a given recording station will consist of $365 \times 24 = 8760$ readings of 8-h running means. We consider such data through the calendar year 2005 for air quality monitoring site in England, namely, Westminster in Central London

Figure 1 Maximum daily readings, Westminster, UK in 2005

(see <http://www.londonair.org.uk/>). Figure 1 plots the daily maximum readings.

Such series tend to have missing values; in England, the Department for Environment, Food, and Rural Affairs set a minimum level of 75% data capture for station records to be included in official returns, though the series under consideration has only 5% missing values. Figure 1 shows a spell of missing values in the early summer months (May, June) when ozone readings are at their highest. We assume missingness at random [78], so that inferences can proceed without modeling the missingness probability mechanism.

We wish to assess the likely range of days with exceedance, namely, days with maximum 8-h running mean exceeding $100 \mu\text{g m}^{-3}$. A predicted exceedance total is required for the actual data since there are missing observations; hence the observed value of 10 exceedances, based on a data capture rate of $8364/8760 = 0.955$, is a minimum. The data can be regarded in several ways: in terms of hour effects repeated each day through the year, individual day effects, month effects, etc.

Preliminary analysis of the data structure suggests both nonconstant means and variances, and while such heterogeneity can be modeled by day specific or even parameters specific to each of the 8760 readings, a relatively parsimonious option assumed here is for month and hour specific effects to define changing means μ_t and log precisions ω_t at the level of readings. For readings over $t = 1, \dots, 8760$ points, let $m = m_t$ ($m = 1, \dots, 12$) and $h = h_t$ ($h =$

$1, \dots, 24$) denote the associated month and hour. The data are then assumed to be truncated normal with

$$y_t \sim N(\mu_t, \exp(-\omega_t))I(0, \infty) \quad (38)$$

$$\mu_t = \alpha_{1m} + \alpha_{2h} \quad (39)$$

$$\omega_t = \gamma_{1m} + \gamma_{2h} \quad (40)$$

where all γ and α parameters are random. To identify the level of the hour effects $\{\alpha_{2h}, \gamma_{2h}\}$ a corner constraint is used, with $\alpha_{21} = \gamma_{21} = 0$. Note that the models for μ_t and ω_t omit an intercept, so that the α_{1m} and γ_{1m} series are identified without a corner constraint being needed. Normal first-order random walks are assumed for the four series $\{\alpha_{1m}, \gamma_{1m}, \alpha_{2h}, \gamma_{2h}\}$, with γ priors on the precisions. See below for the code.

For future planning what is of relevance is the predicted exceedance total over the whole year adjusting for the 4.5% data loss. This has mean 10.6 with 95% interval (10, 12). Also relevant to assessing uncertainty in the annual exceedance total is the posterior predictive density $p(y_{\text{rep}}|y)$ where in the present analysis y includes both observed and missing readings, $y = (y_{\text{obs}}, y_{\text{mis}})$.

A two chain run of 10 000 iterations with diverse starting values is made, with convergence apparent early (within 500 iterations). Model checks using the method of Gelfand [79] are satisfactory. The expected mean exceedance total from the posterior predictive density $p(y_{\text{rep}}|y)$ is 13.5, with a 95% interval from 7 to 21 days. Figure 2 contains the posterior density

Figure 2 Posterior predictive density for exceedances

of the predicted number of exceedances. One might go on to investigate questions such as the chance of more than 15 exceedances in a year or five or more in any particular month. Figure 3 plots the posterior means and 95% credible intervals for the month effects α_{1m} in the level of ozone. This makes the strong monthly variations clear. It may be noted finally that other approaches to analyzing air quality are possible; for example, Raftery [80] adopts a

Bayesian model which considers days between ozone exceedances as a Poisson process.

Arsenic in Drinking Water and the Associated Cancer Risk

A 1999 study by the National Academy of Sciences [81] found that arsenic in drinking water causes bladder, lung, and skin cancer, and may also cause

Figure 3 Plot of α_{1m} parameters

kidney and liver cancer. It estimated that daily ingestion of water containing $50 \mu\text{g l}^{-1}$ of arsenic would add about 1% to a person's lifetime risk of dying from cancer. Morales *et al.* [82] undertook an analysis of cancer risk in relation to a US congress requirement on the US Environmental Protection Agency to revise its standard for arsenic in drinking water below the $50 \mu\text{g l}^{-1}$ level which was then in place. They made a risk assessment for cancers of the bladder, liver, and lung resulting from differing exposure level to arsenic in water. This was based on accumulated cancer mortality data from 42 villages in South West Taiwan relying on well water subject to arsenic contamination. The comparison population is from the same region but with access to uncontaminated water. Relevant data appears in Table A10 of the NRC report and in Table 2 of Morales *et al.*

The data consist of cancer deaths for 13 adult age bands (20–24, 25–29, ..., 80–85) in the 42 villages and the background population with zero exposure – so there are $43 \times 13 = 559$ data cells. The 43 populations are denoted $v = 1, \dots, 43$ and the age-groups are denoted $t = 1, \dots, 13$. The analysis by Morales *et al.* uses Poisson regression of cancer deaths y_{vt} over 1973–1986 in relation to population years P_{vt} exposed to risk. The predictors are centered ages of each band (i.e., 22.5 for the first band, up to 82.5 for the last) and the exposure level, x_v , in each population in micrograms per liter. These

range up to over $900 \mu\text{g l}^{-1}$ in one population. Ages are transformed to be centered and standardized, with a_t denoting transformed age. There are 38 different exposure levels since some villages had equal exposures. Thus $y_{vt} \sim \text{Po}(h_{vt} P_{vt})$, and we follow one of the model forms used by Morales *et al.* assuming independent effects of age and exposure, namely, a quadratic exponential age effect and a linear dose effect. Let $x = x_v$ be the exposure in population v then the hazard (mortality) rate in population v at age t is

$$h_{xt} = (1 + \gamma x)(\exp(\beta_1 + \beta_2 a_t + \beta_3 a_t^2)) \quad (41)$$

Let q_t be life table death rates (for 5 year age-groups t), which Morales *et al.* take from a life table for the United States in 1996. Then the lifetime risk LR_x at exposure x of mortality from a particular cancer or group of cancers over the course of a typical lifetime can be calculated by integrating the hazard h_{xt} over t , i.e., over the typical lifetime. So

$$\begin{aligned} LR_x &= \int_0^\infty h_{xt} S_t dt \\ &\approx 1 - \sum_t q_t \exp\left(-5 \sum_{r \leq t} h_{xr}\right) \end{aligned} \quad (42)$$

where S_t is the probability of surviving till age t .

Here we consider female bladder cancer and consider the predicted risk and its 95% credible intervals at exposures $x^* = \{0, 5, 10, \dots, 500\} \mu\text{g l}^{-1}$.

Figure 4 Lifetime bladder cancer mortality risk (F)

```
model { for (i in 1:559) {y[i] ~ dpois(mu[i]); mu[i] <- h[i]*P[i]
                                h[i] <- h1[age[i]]*h2[expos[i]]}

for (t in 1:13) {h1[t] <-
exp(beta[1]+beta[2]*a[t]+beta[3] *pow(a[t],2))}
for (x in 1:38) {h2[x] <- 1+gam*e[x]}
# cum hazard
for (x in 1:101) {H[x,1] <- haz[x,1]
                  estar[x] <- (x-1)*5
# hazards by age and exposures 0,5,10,.500
for (t in 1:13) {haz[x,t] <- h1[t]*(1+gam*estar[x])}
for (t in 2:13) {H[x,t] <- H[x,t-1]+haz[x,t]}
for (x in 1:101) {LR[x] <- 1-sum(r[x,]); RLR[x] <- LR[x]/LR[1]
# check if excess risk over 10%
                  p10[x] <- step(RLR[x]-1.1)
for (t in 1:13) {r[x,t] <- q[t+1]*exp(-5*H[x,t])}}
# priors
gam ~ dnorm(0,0.001); beta[1] ~ dnorm(-10,0.001);
beta[2] ~ dnorm(0,0.001); beta[3] ~ dnorm(0,0.001)}
```

Figure 4 plots the lifetime risk at exposures up to $500 \mu\text{g l}^{-1}$. The excess risk relative to the zero exposure group and the probability (for various levels of x) that the excess risk exceeds 10% are also derived. Analysis is by the WINBUGS code (see above):

The parameter γ has a mean (95% interval) of 0.032 (0.024, 0.041) and so it is clear that the risk of cancer increases with arsenic exposure. We find a 36% posterior probability that a $15 \mu\text{g l}^{-1}$ exposure leads to 10% excess risk and a

96% probability that a $20 \mu\text{g l}^{-1}$ exposure leads to 10% excess risk. Exposures of $25 \mu\text{g l}^{-1}$ and above have a 100% probability of leading to 10% excess risk.

PETER CONGDON

Behavioral Decision Studies

Probability judgments are an important part of our daily lives. Considering the conclusions we draw from observations, the arguments we make in discussions, and the decisions we make, accurate probability judgments often determine the success of our actions and decisions. Probability judgments are at the heart of many of our core life decisions: What is the probability of getting a grant? What is the probability of winning a law suit? What are the chances of successfully implementing a software system or launching a new product line?

The common denominator of many studies in psychology is the assumption that human probability judgments are often biased [1]. People, for instance, overestimate low probabilities [2], think bad things will happen to others but not to themselves [3], or simply rely on a few salient observations instead of many, representative ones [4]. In this review, we question this view and present evidence of humans' remarkable capacities in judging probabilities.

From an abstract point of view, probability judgments often take the form of one of the following questions: What is the probability that an object X is part of class Y ? What is the probability that a particular event E is the consequence of a process P ? Or, more generally: what is the probability that event E will occur? We discuss the cognitive mechanisms that allow people to answer these questions and show that people often do so fairly adaptively. We start with people's judgments for single risks, continue with probability judgments for combined events, and then discuss how and when people use base-rate information. We close by presenting evidence that imperfect judgments can, nevertheless, be adaptive.

Judging Single Risks

When asked to estimate the frequency of a risk such as a car accident or a flood, people make a frequency judgment for the occurrence of that particular event. The question is, can people judge risk frequencies correctly, or do biases occur? In one classic study, participants estimated the mortality rates of various risks (in the United States), including floods, tornadoes, and homicide [2]. The results reveal two different

phenomena (Figure 1): First, people overestimate rare risks, such as death from botulism or smallpox vaccination, and they underestimate frequent risks, such as cancer or strokes. Overestimation of rare and underestimation of frequent risks can be seen as incidences of biased risk judgments. Second (and this is in contrast to the first point), people judge risk frequencies rather accurately. This claim is supported by a correlation of $r = 0.74$ between objective risks and people's judged risk frequencies [5]. Following the convention in the social sciences that correlations larger than $r = 0.50$ are considered strong, one can conclude that people perceive risk frequencies very accurately. That is, they can predict a rank order of risks very well. Taken together, systematic misperception of risk frequencies and accurate risk perception go hand in hand and are not contradictory. Several explanations have been offered for the two phenomena. The most prominent are regression to the mean [6] and the availability heuristic [4].

Regression to the mean is a common phenomenon in the social sciences and refers to the fact that extreme values (i.e., both low and high ones) tend to the mean [6, 7]. *Floor* and *ceiling* effects have been offered as one explanation for regression to the mean. A floor effect occurs when data cannot fall short of a particular value, and a ceiling effect occurs when data cannot surpass a particular value. Floor effects can explain why rare risks are overestimated, because a floor of zero occurrences constitutes a lower bound. A rare event, thus, is more likely to be over- than underestimated. Floor effects can explain why people in Lichtenstein *et al.* study [2] overestimated rare risks (Figure 1). Ceiling effects are more problematic here, because frequency estimates have no definite upper bound. That is, whereas floor effects might explain the overestimation of rare risks, ceiling effects cannot explain the underestimation of frequent risks.

A more fruitful explanation of regression to the mean asserts that the phenomenon is a necessary consequence as soon as two variables do not correlate perfectly [8]. Suppose a person knows nothing about the frequencies of the various risks. If this is the case, the line depicting this person's risk judgments would be completely flat (i.e., slope = 0), because all risks will be judged equally probable. The more the person knows, the steeper the curve will be. In an uncertain world, however, the person will not learn perfectly and the curve's slope will remain lower than 1. As long as the correlation between objective risks and

Figure 1 Relationship between estimated and actual number of deaths per year for 41 causes of death. The curved line is the best-fitting quadratic regression line. From “Judged frequency of lethal events” [Reproduced from [2]. © American Psychological Association, 1978.]

the person’s risk judgments is imperfect (i.e., $r < 1$), regression to the mean must occur.

In summary, regression to the mean is one explanation for people’s “accurate and biased” judgments of risk frequencies. Although floor effects can explain the overestimation of rare risks, ceiling effects cannot explain the underestimation of frequent ones. The imperfect correlation between objective and judged risk frequencies, thus, best explains regression to the mean.

Another explanation for people’s biased and accurate risk perceptions ([2]; Figure 1) is referred to as the availability heuristic [2]. One might judge the frequency of a class or the probability of an event by the ease with which examples or occurrences can be brought to mind. For example, one may assess the probability of a motor vehicle accident by recalling such occurrences among one’s acquaintances, friends, or family members. From an abstract perspective, the availability heuristic is used to answer questions of the following type: How many objects *X* of the type *Y* are there? How common is event *E* under condition *C*? In general, the availability heuristic is quite useful for judging risk frequencies – as supported by the high correlation between objective and judged risk frequencies in Figure 1.

When is a risk cognitively available and when is it not? Or, to put it differently, which factors

influence the availability of risks? Factors such as (a) disproportionate exposure, (b) imaginability, and (c) ease of retrieval have been suggested to determine the availability of risk [2, 9].

Disproportionate exposure means that the newspapers, for instance, report disproportionately more often about spectacular risks, such as tornados, than about unspectacular risks, such as strokes or stomach cancer. Disproportionate media exposure, then, triggers availability, which causes people’s overestimation of risks [2].

Imaginability means that events that are easy to imagine are cognitively more available than events that are difficult to imagine. For instance, most people can better imagine a tornado than stomach cancer. Consequently, a tornado’s higher availability could explain its biased frequency judgment [2].

Ease of retrieval refers to the ease with which relevant instances can be brought to mind, rather than the sheer number of recalled instances that determines risk judgments [9]. Imagine one group of people is asked to write down three things that increase the risk of cancer. Another group is asked to write down eight things. Then both groups are asked how likely it is to die from cancer. Which group will give the higher probability estimate? The availability heuristic would predict that the group that wrote down eight causes would give a higher probability

estimate than the group that listed only three. Yet this is not always the case: whereas it is easy to retrieve three causes, it is difficult to retrieve eight causes. People in the three-causes group may think that because it is so easy to retrieve three causes, cancer seems rather likely. People in the eight-causes group may think that because it is so difficult to retrieve eight causes, cancer seems rather unlikely. Paradoxically, despite more evidence (eight rather than three causes), people give lower risk estimates. Similar effects have been found in other domains [10, 11]. In sum, both regression to the mean and the availability heuristic explain people's "accurate and biased" risk judgments well [5].

Judging Risks for Combined Events

Up to now, we have covered judgments of single rather than combined events. We now turn to risk judgments for combined events, which can be either conjunctive or disjunctive. We start with risk judgments for conjunctive events.

Judging Risks for Conjunctive Events

Conjunction effects have been debated extensively in the context of probabilistic judgments. For illustrative purposes, consider the following experimental task [12]:

A health survey was conducted in a representative sample of adult males in British Columbia of all ages and occupations. Mr. F. was included in the sample. He was selected by chance from the list of participants. Which of the following statements is more probable? (Check one)

Mr. F. has had one or more heart attacks.

Mr. F. has had one or more heart attacks, and he is over 55 years old.

According to probability theory, the conjunction of two events cannot exceed the probability of either single event, that is, $p(A \& B) \leq p(A), p(B)$. Yet 58% of statistically naive respondents did not find the correct answer in this task. Rather, a conjunction error occurred; that is, they thought the conjunction – Mr. F. has had one or more heart attacks and he is over 55 years – to be more likely than the single event.

The reason for this error is attributed to the representativeness heuristic [12]. That is, older people

(in the experimental task those who are older than 55 years) are more likely to have already encountered one or more heart attacks than people who are younger than 56. To put it differently: heart attack seems to be more representative for older people.

What is available in people's minds is the co-occurrence of the two events. As a consequence, when asked to evaluate whether a person has had one or more heart attacks and is also over 55 years, people often overestimate the co-occurrence of the events. Indeed, to evaluate the co-occurrence of the events more accurately, a person has to think of four groups: (a) people who have had one or more heart attacks and are over 55 years, (b) people who have had one or more heart attacks and are younger than 56, (c) people who have never had a heart attack and are over 55 years, and (d) people who have never had a heart attack and are younger than 56 years. People, however, tend to focus on the group in which both events occurred (a) and neglect those groups that fall into one of the other three combinations.

Is it the representativeness heuristic that causes the conjunction fallacy? Evidence has emerged that in natural language, terms such as "and" (in the second statement of the experimental task) are semantically ambiguous [13, 14]. That is, in a fair test, the phrase "and" must have the same meaning in probability theory as it does in natural language. In probability theory "and" refers to an intersection only, but in natural language "and" refers to either a union or an intersection. For instance, the sentence "We invited friends and colleagues to the party" refers to a union, not to an intersection, of friends and colleagues. There is agreement that (a) the semantic ambiguity of "and" is a factor that contributes to conjunction effects, and (b) certain conditions can override the representativeness heuristic [14].

Judging Risks for Disjunctive Events

Conjunctive events refer to the intersection of two or more events. Disjunctive events refer to the union of two or more events. The disjunction of two or more events can be either implicit or explicit. Imagine, for instance, you are asked to judge your likelihood of dying from cancer (implicit disjunction). Suppose further you are asked to judge your likelihood of dying from skin cancer *or* colorectal cancer, *or* stomach cancer (explicit disjunction). Obviously, there are more than three kinds of cancer. Whereas the implicit

disjunction (cancer) covers all kinds of cancers, the explicit disjunction does not. Consequently, normative theory predicts higher likelihood estimates for the implicit than for the explicit disjunction.

Yet this is not the case. Researchers have found that people's likelihood estimates of the implicit disjunction (cancer) are *lower* than the likelihood estimates of the explicit disjunction (skin cancer, etc.). This phenomenon is called *subadditivity* [15], and it has been found for both students and experts [16]. Psychologically, the explicit disjunction reminds people of the different cancers one can die of, making them cognitively more accessible. Because of this cognitive accessibility, the probability estimate is higher for the explicit than the implicit disjunction.

Cognitive accessibility, however, is not the only mechanism that can explain subadditivity. Imagine an experiment in which Group 1 receives the following question:

What is the probability that you will die from skin cancer *or* stomach cancer?

Group 2 receives the following two questions:

What is the probability that you will die of skin cancer?

What is the probability that you will die of stomach cancer?

Whereas Group 1 receives the disjunction, Group 2 receives the constituents. Does the sum of the constituents' probabilities (Group 2) equal the probability judgment of the disjunction (Group 1)? Research indicates subadditivity is at work again. That is, the probability estimate for the disjunction (Group 1) falls short of the sum of the separate probability estimates for the constituents (Group 2; [17]). Accessibility, however, cannot explain subadditivity here, because for both groups the constituents were mentioned explicitly. The mechanism at work must be a different one that is commonly referred to as anchoring and adjustment [18].

Initially, both groups proceed in the same way by separately judging the probability of each kind of cancer. Group 1, in addition, has to combine these probability judgments (anchors), which are, importantly, lower than the overall probability of the disjunction. Participants may not fully detach from these lower probability estimates and arrive at an estimate for the disjunction that is subadditive. That is, anchoring

(initial probability estimates) and insufficient adjustment (sticking to these anchors) may explain subadditivity. In sum, disjunctive events are subadditive, and (a) cognitive accessibility and (b) anchoring and adjustment can explain this phenomenon.

Do People Ignore Base Rates?

An important question is whether people are insensitive to prior probabilities of outcomes – in other words, do they ignore base-rate information? Consider the following experiment [19]:

A cab was involved in a hit-and-run accident at night. Two cab companies, the Green and the Blue, operate in the city. You are given the following data:

- (a) 85% of the cabs in the city are Green and 15% are Blue.
- (b) A witness identified the cab as Blue. The court tested the reliability of the witness under the same circumstances that existed on the night of the accident and concluded that the witness correctly identified each one of the two colors 80% of the time and failed 20% of the time.

What is the probability that the cab involved in the accident was Blue rather than Green?

Using Bayes' theorem (*see Bayes' Theorem and Updating of Belief*), one can calculate the correct posterior probability $p(H|D)$, where H and $\neg H$ denote the two possible outcomes (i.e., Blue or Green) and D denotes the reliability of the witness (i.e., 80% in the above experiment). If the values are given in the standard probability format (as in the experiment), the posterior probability can be calculated by solving the following equation:

$$\begin{aligned} p(H|D) &= \frac{p(H)p(D|H)}{[p(H)p(D|H) + p(\neg H)p(D|\neg H)]} \\ &= \frac{(0.15)(0.80)}{[(0.15)(0.80) + (0.85)(0.20)]} \end{aligned} \quad (1)$$

The result is $p(H|D) = 0.41$. Hence, despite the report of the witness, the hit-and-run cab is more likely to be Green than Blue. The reason for this result is that the base rate (0.15) is rather low. When asked to judge the probability that the cab involved in the accident was Blue rather than Green (i.e., the posterior probability $p(H|D)$), people typically gave median responses of $p = 0.80$. This probability judgment resembles the reliability of the witness but ignores base-rate information. According

Figure 2 Bayesian inference and information representation. Natural sampling of frequencies (a) and standard probability format (b). From “How to improve Bayesian reasoning without instruction: Frequency formats” [Reproduced from [21]. © American Psychological Association, 1995.]

to the “heuristics-and-biases” program, Bayes’ theorem is no longer expected to describe the workings of the mind, and people’s poor performance has been attributed to the mind’s limited information-processing abilities [20].

However, it was not long before the first experiments were conducted to challenge the view of the mind as a poor Bayesian performer [21, 22]. If frequency information is presented in absolute frequencies rather than in abstract probabilities, people’s judgments often come up to the predictions of Bayes’ theorem. Consider the following task [21]:

Imagine an old, experienced physician in an illiterate society. She has no books or statistical surveys and therefore must rely solely on her experience. Her people have been afflicted by a previously unknown and severe disease. Fortunately, the physician has discovered a symptom that signals the disease, although not with certainty. In her lifetime, she has seen 1000 people, 10 of whom had the disease. Of those 10, 8 showed the symptom; of the 990 not afflicted, 95 did. Now a new patient appears. He has the symptom. What is the probability that he actually has the disease?

Presented in this way, that is, in absolute frequencies rather than in abstract probabilities, Bayes’ theorem reduces to a simple natural sampling tree, as shown

in Figure 2(a). All the physician needs is the number of cases that had both the symptom and the disease (8) and the number of cases that had the symptom but no disease (95) and their sum ($8 + 95$). Presented in the standard probability format, in contrast, Figure 2(b) shows that the calculation of the correct answer is much more intricate.

The findings from a series of experiments clearly show that people can perform Bayesian reasoning if information is presented in a frequency format [21, 23]. Specifically, when presented with a frequency format, 46% of the participants considered base rates and answered in line with the correct Bayesian solution; presented with a standard probability format, this proportion dropped to only 16%. In sum, information representation affects cognitive algorithms. Frequency formats made many participants follow Bayes’ theorem without any teaching or instruction. When information is presented appropriately, people do consider base rates more often.

Are Judgments Drawn from Small Samples Valid?

In the real-world people have to rely on a limited rather than an unlimited number of observations. This

number of observations, that is, the sample size, has been the focus of much research in psychology [1]. Normatively, the laws of statistics prescribe that conclusions drawn from a small sample are less reliable than conclusions drawn from a large sample. Do people consider the size of a sample when they judge the likelihood of events?

The answer seems to be no – at least suggested by one stream of research [24]. Consider the following demonstration: Empirically, in the whole population the mean height of men is 6 ft. From this population, samples of the sizes 10, 100, and 1000 are drawn. Normatively, the mean of a small sample is more likely to deviate from the population mean than the mean of a large sample. Therefore, people are expected to estimate a higher probability of getting a mean height larger than 6 ft (i.e., the population mean) for the small (10) sample than for the large (1000) sample. Yet in one study, in contradiction of this normative rule, participants estimated *equal* probabilities of getting a mean height larger than 6 ft for all three samples sizes (10, 100, and 1000). Obviously, in this experiment they did not consider sample size. In another experiment, squash players answered the following question [25]:

As you know, a game of squash can be played to either 9 or 15 points. Holding all other rules of the game constant, if A is a better player than B, which scoring system will give B a better chance of winning?

All participants had some knowledge of statistics. In contradiction of the normative rule, most participants said that the scoring system should not make any difference. Considering the argument that an atypical outcome is more likely to occur in a small sample than in a large one, it is obvious that the probability of winning is higher for player B when the game is played to 9 rather than 15 points. From this and similar experiments, it has been concluded that people “neglect sample size” and rely on judgments from samples that are too small. Yet, one might wonder whether conclusions from small samples might have some advantages, too.

Indeed, empirical research has found evidence for the benefits of drawing conclusions from small sample sizes [26]. A small sample of the size of 7 ± 2 , Kareev argued, is most likely to produce a sample correlation that is more extreme than the correlation of the population. On the basis of Miller’s

work on the limited number of items people can consider at one time [27], Kareev argued that capacity limitations help people maximize the chances of early detection of strong and useful relations [26]. The question of when and how this benefit occurs is currently an issue of hot debate [28–30].

Judging Personal Risks: Unrealistic or Adaptive?

Imagine you are asked to estimate your personal risk of confronting a certain event in your life, for instance, getting divorced. In particular, you are requested to judge whether your risk of getting divorced is higher, the same, or lower than that of a comparable person. In experiments such as this, normative theory predicts that half of the participants will evaluate their risk to be above a comparable other person, and the other half below. In contrast to this prediction, most participants give lower rather than higher risk estimates. That is, they think that others, but not themselves, will get divorced and thus they show *unrealistic optimism* [3]. Similar results were found for other negative events, such as committing suicide or dying from cancer.

For positive events, in contrast, probability judgments reverse: most people think that they are more likely to experience positive events than comparable other persons. For example, most people think that their chances of owning a home or winning an award for their work are higher than those of comparable others. People thus show unrealistic optimism again. This research suggests that people are poor judges of their future risks and prospective opportunities. Clearly, underestimating risks and overestimating opportunities can lead to severe consequences. People may forgo medical screening tests or unwisely invest money, time, and effort in projects having little chance of success. High expectations, furthermore, can lead to more disappointment, if these expectations are not met. Modest expectations, in fact, are generally believed to enhance one’s happiness. In sum, misperceiving one’s risks and opportunities may have severe consequences.

Does unrealistic optimism indeed impede human functioning? No. A very large body of research shows that optimistic people are better off. Optimistic people are more motivated than realistic people, especially after a decision is made, and optimism rises after decisions [31]. Such postdecisional optimism makes

sense, because questioning one's decision may only undermine one's energy and motivation, which is needed for implementing the decision.

Optimistic people, moreover, achieve better outcomes than realistic people. That is, they are more successful or earn more money than realistic people [13, 32]. Because of their higher expectations, however, they rarely reach their goals. Missing one's goals is generally believed to cause disappointment. Paradoxically, if optimistic people miss their goals, they are *less* disappointed than realistic people [33, 34], because they interpret their failures less negatively than realistic people do. In sum, compared to realistic people, optimistic people (a) are more motivated after a decision, (b) achieve better outcomes, (c) miss their goals more often because of their higher expectations, but (d) paradoxically, are less dissatisfied if their goals have not been met – in short, optimists are unrealistic and adaptive.

Does Irrelevant Information Affect Probability Judgments?

People often estimate risks by starting from an initial value. Usually, this initial value, or anchor, is adjusted to reach a final risk estimate [18]. Anchoring and adjustment describes this process. In one study, for example, participants were asked to estimate the probability of a war between the United States and the Soviet Union [35]. One-third of the participants were asked to judge whether the probability of such a war was smaller or larger than 90%. The second third of the participants were asked to judge whether the probability was smaller or larger than 1%. The remaining third got no anchor. Then, participants estimated the probability of war between the two countries. As expected, participants with an anchor of 90% gave higher probability estimates than participants with no anchor, who gave higher estimates than participants with an anchor of 1%. Similar anchoring effects were found in other domains, too [36–39].

What conditions cause anchoring effects? Research has identified several [40, 41]: scale compatibility, category compatibility, and extremity of the anchor. *Scale compatibility* means that anchoring effects are stronger when the anchor's metric and people's subsequent estimates are on the same scale. In the example above, for instance, both the initial anchors (90% or 1%) and participants' subsequent probability estimates are on the same (probability)

scale. The anchoring effect would be smaller, say, if participants had to judge whether a certain line was shorter or longer than 1 cm (90 cm) and then state their probability estimate for a war between the United States and the Soviet Union.

Category compatibility means that people show stronger anchoring effects when the anchor's metric and the metric of the subsequent estimate belong to the same category than when they do not [38]. Anchoring effects, would be smaller, for example, if people estimated at first whether the probability of an atomic power plant accident was lower or higher than 90% (1%) and then estimated the probability of a war between the United States and the Soviet Union. Note that both estimates belong to the same scale (probability) but not to the same category (atomic power plant accident *versus* war).

Even *extreme anchors* influence people's judgments [38]. Common wisdom tells us that extreme anchors should be less effective than moderate ones, because people would judge them as implausible. In contrast to this intuition, extreme and implausible anchors produced anchoring effects that were just as large as moderate and plausible ones. That is, even extreme anchors such as 99.9999 or 0.0001% would produce anchoring effects in the war example.

Incentives, however, have influenced anchoring effects very little, if at all [18, 39]. That is, in laboratory experiments anchoring effects were not reduced when people's payoffs depended on the accuracy of their final estimates.

The research reviewed above suggests the pessimistic view that irrelevant numerical values (anchors) bias people's probability judgments. Anchors produce assimilation effects, because people's probability judgments tend toward the initial anchor. A different conclusion emerges, however, if we do not consider the estimated probability values but the subjective impressions of these probability values [42]. For the subjective impressions of probability, a contrast rather than an assimilation effect occurs.

Suppose one group of people is asked whether the probability of war is greater than 1%. Another group is asked whether the probability of war is smaller than 90%. Then both groups estimate the probability of war. Because of anchoring and adjustment, the 1% group will give lower probability estimates than the 90% group; thus an assimilation effect has occurred. If asked, however, whether the estimated probability is low or high, a contrast effect occurs: for the

first group, 1% serves as a reference point and any increase is perceived as high; for the second group, 90% serves as a reference point and any decrease is perceived as low. Paradoxically, then, the 1% group will give lower probability estimates than the 90% group, but the 1% group will perceive their estimates to be higher than the 90% group will perceive theirs. These results match other findings that show, for instance, that Olympic athletes who won the bronze medal are happier than athletes who won the silver medal, because bronze medalists compared themselves to athletes who finished fourth, whereas silver medalists compared themselves to the gold medalists who finished first [43]. In sum, anchoring effects can be paradoxical: an assimilation effect in one direction may be compensated for by a contrast effect in the other direction. A clear bias, thus, is not evident.

Conclusion

Probability judgments play a key role in our coping with our daily lives. The common denominator of much research in decision science is the assumption that human probability judgments are often biased. Although this is correct for some specific instances, in this review we presented evidence that this assumption seems to be too narrow. People, for instance, assess the frequencies of causes of death quite accurately ($r = 0.74$), consider base rates and thus follow Bayes' rule if frequency information is presented in absolute frequencies rather than abstract probabilities, or compensate for assimilated frequency judgments (anchoring and adjustment) by forming subjective impression that reverse their biased judgments. In real life, in which the correct normative solutions are most often not known, heuristics are useful tools for making fast and frugal judgments and decisions [21, 44].

Benchmark Analysis

Benchmark analysis is a statistical procedure applied to dose–response data from toxicologic, clinical, or epidemiologic studies that can be useful in setting health guidelines for exposures to toxic substances. Such guidelines include those promulgated by the United States Environmental Protection Agency (USEPA) called *reference doses* (RfDs) for oral exposures, or *reference concentrations* (RfCs) for exposures through the ambient air. The USEPA defines the RfD as an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population, including sensitive subgroups that is likely to be without an appreciable risk of deleterious effects during a lifetime [1].

Previously, an RfD or RfC was based on a no-observed-adverse-effect-level (NOAEL – the largest dose or exposure at which no adverse health response was observed), which is the largest exposure or dose at which no statistically or biologically significant adverse effect has been identified, and which is also smaller than any dose or exposure at which an adverse effect has been noted. Once a NOAEL is determined, the RfC or RfD is calculated by converting the NOAEL to an equivalent human exposure, and then dividing by uncertainty factors that account for various types of shortcomings in the data base.

There are several potential shortcomings to this NOAEL approach to setting exposure guidelines:

1. The shape of the dose–response curve (*see Dose–Response Analysis*) is not taken into account in determining a NOAEL. Also, the NOAEL must be one of the experimental doses. In an experiment with a steep dose–response, in which a marginally significant response occurred at a particular dose, it may appear highly likely that no response would have been seen at, e.g., a twofold lower dose. However, the NOAEL would be defined as the next lower experimental dose, which could be 10-fold or more lower.
2. All other things being equal, a smaller study should result in a lower exposure guideline because it entails more uncertainty. However, the NOAEL from a smaller study tends to be larger

because a smaller sample size makes statistical significance less likely to be established.

3. Application of the NOAEL approach is problematic in cases in which an adverse response occurred at the smallest experimental dose, so that a NOAEL is not determined.
4. Deciding whether a particular dose is a NOAEL can be controversial. For example, for the data set in Table 1, the response at 10 ppm (9/50) is not statistically different from that in unexposed subjects (5/50) ($p = 0.19$), so that 10 ppm could be considered to be the NOAEL. On the other hand, since the response at 10 ppm is higher than that in unexposed subjects, and appears to be consistent with the dose–response suggested by the increased responses at 15 and 20 ppm, 5 ppm could alternatively be considered to be the NOAEL. How such controversy is resolved can have a large effect upon an exposure guideline.
5. The NOAEL approach is most readily applicable to data from toxicological or clinical studies (*see Toxicity (Adverse Events)*) in which test subjects are distributed into groups whose subjects all have a common exposures. It is not straightforward to apply the approach to epidemiological data, where each subject can have a unique exposure. Also, in some epidemiological studies there is no unexposed group to compare with exposed groups.

The benchmark approach was proposed as an alternative to the NOAEL approach in setting exposure guidelines [2, 3]. The benchmark dose (BMD – defined as the dose that causes a specified increase in the risk, or probability, of an adverse response) is the dose or exposure that corresponds to a specified increase in risk (called the *benchmark risk* or *BMR*, level of increased risk (e.g., 0.1) used in the definition of the BMD) over the risk in an unexposed population. It is estimated by fitting a mathematical dose–response model to data. A statistical lower bound on the BMD (BMDL – statistical lower bound on the BMD) replaces the NOAEL in determining an exposure guideline. The USEPA uses the BMD method for determining RfDs and RfCs for noncancer responses [1]. Also, the USEPA guidelines for cancer risk assessment specify the determination of an AED₁₀, which is equivalent to a BMD corresponding to a BMR of 0.1 [4].

Table 1 Example of BMD calculation from binary data^(a)

Dose (ppm)	Number of animals	Number of responders		
		Observed	Predicted	
			Weibull	Logistic
0	50	5	5.26	4.89
5	50	4	5.29	5.12
10	50	9	6.56	7.12
15	50	15	16.5	16.1
20	50	45	39.6	39.7
BMD ^(b)	—		12.8	12.4
BMDL ^(c)	—		10.1	9.7

^(a) Reproduced from [2]. © John Wiley & Sons, Ltd, 1984

^(b) Maximum – likelihood estimate of BMD using $BMR = 0.1$

^(c) Ninety – five percent of statistical lower bound on BMD computed by the profile likelihood method [5–7]

The BMD approach addresses the shortcomings of the NOAEL mentioned above:

1. The BMDL takes into account the shape of the dose–response through the fitted dose–response model, and the BMDL is not constrained to be one of the experimental doses.
2. Because the BMDL accounts for statistical variation, smaller studies tend to result in smaller BMDLs.
3. The BMDL can be calculated from a study in which an effect was seen at all doses.
4. The determination of a BMDL does not involve the potentially controversial decision of determining whether an effect was present at a particular dose.
5. The BMD approach can be applied to either grouped or ungrouped data, and does not require an unexposed group.

On the other hand, the BMD approach involves issues that are not present in the NOAEL approach:

1. The BMDL may depend upon the particular mathematical dose–response model used.
2. The level of risk (BMR) used to define the BMD must be decided upon.
3. Different modeling approaches, and perhaps different definitions of risk (*see Absolute Risk Reduction*), are required for continuous responses (such as blood pressure which can theoretically assume any value in a range) than for binary

responses (which indicate only whether or not a particular effect was present).

The BMD is defined as a dose that corresponds to a specified increase in risk, whereas the NOAEL is sometimes viewed as a dose that truly had no effect, rather than a dose at which no effect was identified (leaving open the possibility that an effect was present that a study with greater statistical power might have detected). For persons with this latter view of the NOAEL, replacing the NOAEL with the BMDL represents a major paradigm shift.

Performing a BMD Analysis Using Binary Data

Let $P(d)$ represent the probability that a subject exposed to a dose of d has an adverse health outcome. We assume $P(d)$ has a mathematical form that involves unknown parameters that are estimated by fitting the dose–response model, $P(d)$, to data. The fitting of the model to data is generally accomplished using the method of maximum likelihood, in which the unknown parameters are selected so that the probability of observing the experimental outcome is maximized [5].

The BMD can be defined as the dose for which the additional risk equals the predetermined BMR, i.e., as the solution to the equation

$$P(BMD) - P(0) = BMR \quad (1)$$

The maximum-likelihood estimate of the BMD is calculated by replacing the unknown parameters by their maximum-likelihood estimates, and solving this equation for BMD. The profile likelihood method is recommended for calculating a statistical lower bound, BMDL, on the BMD [5–7].

Dose–Response Models for Binary Data

A number of different dose–response models have been proposed for use in BMD calculations [8, 9]. Examples include the Weibull model,

$$P(d) = 1 - \exp[-\alpha - (\beta d)^K], \quad \alpha, \beta \geq 0, K \geq 1 \quad (2)$$

and the logistic model,

$$P(d) = 1 - \frac{1}{[1 + \alpha + (\beta d)^K]}, \quad \alpha, \beta \geq 0, K \geq 1 \quad (3)$$

where α , β , and K are the parameters estimated by fitting the model to data [5, 6, 8, 9]. In each model, α specifies the background response, β gauges the potency of the substance for causing the health effect, and K determines the shape of the dose–response. Both of these models can be expanded to include covariates such as age and gender.

The inclusion of the shape parameter, K , permits these models to be nonlinear. The restriction, $K \geq 1$, is recommended with each model in order to rule out biologically implausible dose–responses that hook up very sharply at very low doses, and which can result in BMDLs that are unrealistically small [10].

Table 1 presents the results of a BMD analysis that applied the Weibull and logistic models (*see Logistic Regression*) to some fabricated toxicological data. The BMR was set equal to 0.1. Although 15 was the lowest dose at which the response was significantly elevated over the response in controls, because the response at a dose of 10 appears to be part of an increasing trend, identification of a NOAEL could be controversial. Both the Weibull and logistic models fit these data adequately. (A χ^2 goodness-of-fit test resulted in a p value >0.4 in both cases.) The BMDLs obtained from the two models were also similar (10.1 using Weibull model and 9.7 using the logistic model).

Figure 1 illustrates the calculation of the BMD maximum-likelihood estimate and the BMDL for the

Figure 1 Illustration of the calculation of the BMD from the data in Table 1, using the Weibull model (equation (2))

Weibull model applied to the data in Table 1. The vertical bars in the figure represent 90% confidence intervals for the response probabilities. The darker curve is the maximum-likelihood fit of the Weibull model, $P(d)$. The parameter values obtained from this fit were $\alpha = 0.12$, $\beta = 0.056$, and $K = 7.3$. The BMD estimate of 13.5 ppm is defined by where the upper horizontal line, placed at a response of $P(0) + BMR = 0.11 + 0.1 = 0.21$, intersects the curve $P(d)$. The lighter curve is the Weibull model, $P^*(d)$, that defines the BMDL (i.e., the Weibull curve determined by parameters corresponding to the BMDL derived using the profile likelihood method [5–7]). The $BMDL = 11.3$ ppm is defined by where the lower (dotted) horizontal line, placed at a response of $P^*(0) + BMR = 0.086 + 0.1 = 0.186$, intersects the curve $P^*(d)$.

Selection of the Risk Level (BMR)

Before the BMD method can be applied, the BMR (level of additional risk resulting from exposure at the BMD) must first be specified. In the example presented above, the BMR was set at 0.1, in keeping with an original proposal by Crump that the BMR be in the range 0.01–0.1 [2]. It is important not to make the BMR so small that the BMD is highly model-dependent. The limited size of most toxicological experiments (50 or fewer animals per group) makes it difficult to reliably estimate doses corresponding to risks as low as 0.01, which suggests that a BMR in

the upper end of this range may be more appropriate. Many of the RfCs and RfDs promulgated by the USEPA based on the BMD have utilized $BMR = 0.1$ [1]. Similarly, the USEPA guidelines for cancer risk assessment incorporate calculation of an ED_{10} , which is equivalent to a BMD corresponding to a $BMR = 0.1$ [4]. For different BMD analyses to be comparable, they should be based on a common value for the BMR.

Model Selection

In addition to the Weibull and logistic models discussed herein, many others could be considered. Models for binary data with no more than three parameters (one for each of background, shape, and potency) will often provide comparable BMDs, so long as the BMR is in the range of risks that can be estimated reasonably well by the data. However, this may not be true for data sets that are sparse or do not demonstrate a strong dose–response. A model that fits the data adequately may be preferred over one that does not, although often several models will provide comparable fits. Because of this, in order to standardize the determination of an exposure guideline, it could be useful to specify a default model to be used so long as it fits the data adequately. The RfCs and RfDs promulgated by the USEPA have often been based upon the Weibull model or the special case of the Weibull with $K = 1$ [1].

Performing a BMD Analysis Using Continuous Data

A simple way to calculate a BMD from continuous data is to first convert the data to a binary form by defining a response to be abnormal if it is more extreme than some predetermined limit, y_0 , and then applying the methods discussed above for binary responses. However, possibly more powerful approaches may be obtained by directly modeling the continuous responses. Such modeling is often carried out using a model that assumes that the (possibly transformed) continuous response is normally distributed, with the mean, and possibly the standard deviation, depending upon the dose. Using such a model, perhaps the simplest approach is to define the BMD as the dose corresponding either to a specified absolute or percentage change in the mean response.

However, this approach does not account for normal variation in a response. For example, a 10% change in red blood cell count is within the range of normal variation, whereas a 10% change in temperature would be fatal. A better way to account for normal variation is to define the BMD as the dose that corresponds to a predetermined change in the mean response normalized by the standard deviation in unexposed subjects [11].

Because both binary and continuous data are often available, it would be helpful to have a common definition of the BMD that can be applied to both types of data. Otherwise, it may not be clear how BMDs determined from the two types of data are related. Suppose that responses larger than a predetermined limit, y_0 , are considered to be adverse. For example, if the response were systolic blood pressure and y_0 was selected as 160, then a systolic blood pressure greater than 160 would be considered to be an adverse response. Alternatively, instead of assuming a fixed limit, y_0 , one could specify a fixed probability, $P(0)$, of an adverse response in an unexposed individual (e.g., $P(0) = 0.05$ in keeping with the convention in clinical testing that the normal range includes 95% of the responses of healthy individuals) of a unexposed subject having an adverse response. With either y_0 or $P(0)$ fixed, the probability of an adverse response in a subject with a dose d can then be calculated using a model for the continuous response suggested above without the need to convert the data to binary form [10–12]. Using this form for the probability of an adverse effect, the BMD can then be defined using equation (1) in a manner analogous to that used for binary data.

Software for BMD Analysis

The calculations needed to implement a benchmark analysis are nonstandard and may be difficult to perform using standard statistical software. Several special-purpose software packages are available for performing benchmark calculations [8, 9, 13].

Benchmark Dose Estimation

Introduction and Background

A primary objective of quantitative risk analysis is the characterization of risk *via* one or more quantitative estimates of the severity and likelihood of damage to humans or to the environment caused by a hazardous agent [1]. In many cases, however, epidemiological or human data on hazardous substances (*see What are Hazardous Materials?*) are not available or are inadequate for quantitative risk assessment. Thus, to assess the potential risk of an exposure to a hazardous agent, bioassays are conducted on laboratory rodents or other biological systems where the dose levels of the substance(s) are administered at relatively high dose levels (*see Cancer Risk Evaluation from Animal Studies*). A major quantitative component of such studies is statistical characterization of the *dose–response* (*see Dose–Response Analysis*) to the toxic agent and, from this, assessing possible risks to humans and setting acceptable reference doses (RfDs) or reference concentrations (RfCs) *via* extrapolation of the results of such bioassays to low-dose ranges usually encountered in environmental exposures.

Traditionally, risk and RfD estimation has been based heavily on a hypothesis-testing procedure where a no-observed-adverse-effect level (NOAEL) and a lowest-observed-adverse-effect level (LOAEL) are generated using multiple comparisons between the control group and the various dose groups. First, the largest experimental dose that is not significantly different from the zero-dose control group (NOAEL) is determined. If the NOAEL is not well defined, the smallest experimental dose that is significantly different from the zero-dose control (LOAEL) is determined. The NOAEL (LOAEL) is considered as an estimator of the dose threshold of the hazard. Next, if the NOAEL is well defined, the RfD is often defined as NOAEL/100. Here the 100 in the denominator of the RfD is called an *uncertainty* or *safety factor* (*SF*) that accounts for interspecies extrapolation of experimental results from animals to humans. To be more specific, 100 is taken as a factor of 10 for animal to human extrapolation, and then a factor of 10 for individual variation in sensitivity (=100).

In the absence of a NOAEL, the RfD is defined as LOAEL/1000, where another factor of 10 is used in the denominator since a NOAEL is not available. The RfD is then used in the regulatory process for setting acceptable levels of human exposure to potentially toxic substances.

Although the NOAEL/SF approach is easy to understand and has an intuitive appeal, it suffers many drawbacks. Examples of such are as follows: the NOAEL must be one of the experimental doses and is known to decrease as the number of replicates increases; it can fail to estimate the potential risk at the RfD, which is usually greater than zero; information on the dose–response relationship is lost since this approach only gives one single summary measure and does not utilize all of the data; it does not take into account the slope of the dose–response curve nor the variability in the estimate of the dose–response; and it is not straightforward to apply to epidemiological data [2–4].

To overcome some of the drawbacks of the NOAEL/LOAEL approach, Crump devised what is now known as *benchmark dose methodology* [2, 5]. In a risk assessment the benchmark dose (BMD) is defined as the point estimate of the effective dose/concentration that would result in a predetermined increase in risk (known as the *benchmark risk* or *BMR*) over the risk in an unexposed population. A statistical lower confidence limit on the BMD is known as the a lower limit on the benchmark dose (*BMDL*) [2]. In 1995, the United States Environmental Protection Agency (USEPA) adopted the BMD approach in setting RfDs and recommends that target BMRs should be between 1 and 10%. In fact, USEPA has developed a general technical guidance and a computer package, known as *BMDS*, to facilitate the application of the BMD method in risk assessment [4, 6].

To apply the BMD methodology, an appropriate statistical model that quantifies, at least approximately, the relationship between exposure level (dose) and response is fit to the experimental data. From this model, we calculate the dose (BMD) that corresponds to the specified risk (BMR) and a lower $100(1 - \alpha)\%$ confidence limit (BMDL) is derived. Defining risk as the probability of some predefined adverse outcome (such as death, weight loss, birth defect, cancer, or mutation) exhibited in a subject exposed the hazardous agent and assuming risk changes with increasing dose or exposure, d , to

the toxic agent, we write this probability as $R(d)$. To correct for the spontaneous risk of response, $R(0)$, additional risk and extra risk functions are frequently used in risk estimation [7–10]. Additional risk, $R_A(d)$, is defined to be the risk beyond that of the control (background, spontaneous) level; that is

$$R_A(d) = R(d) - R(0) \quad (1)$$

In some instances, additional risk is further corrected into extra risk to account for nonresponse in the unexposed population. Extra risk, $R_E(d)$, is defined as the additional risk among subjects who would not have responded under control conditions:

$$R_E(d) = \frac{R_A(d)}{1 - R(0)} \quad (2)$$

Notice that equation (2) assumes $0 \leq R(0) < 1$.

The BMD for Quantal Response Data

With quantal data, a subject is classified as exhibiting an adverse health effect or not and the proportion of subjects exhibiting the effect is recorded. These data are very common in carcinogenesis, teratogenesis, and mutagenesis studies [7, 11–13]. The usual assumption under this setting is that the number of subjects exhibiting an adverse response is binomially distributed. Formally, let $d_1, d_2, \dots, d_k$ be the k dose groups employed, $N_1, N_2, \dots, N_k; n_1, n_2, \dots, n_k$ be the total and responding subjects in the i th dose group, respectively, and $p_i = p(d_i, \Theta)$, $i = 1, 2, \dots, k$ the probability of response to dose i where Θ is a vector of parameters in the posited dose–response model. To find the maximum-likelihood estimator, $\hat{\Theta}$ of Θ , we can maximize the log-likelihood function $L(\Theta) = \sum_{i=1}^k (n_i \ln(p_i) + (N_i - n_i) \ln(1 - p_i))$. Then for a specified $BMR = R^*$, and using extra risk to account for the risk beyond background risk, the estimated BMD ($\hat{BMD}$) is obtained by solving the following equation:

$$R^* = \frac{p(BMD; \hat{\Theta}) - p(0; \hat{\Theta})}{1 - p(0; \hat{\Theta})} \quad (3)$$

Alternatively, if additional risk is used, the $B\hat{M}D$ is the solution to the equation:

$$R^* = p(BMD; \hat{\Theta}) - p(0; \hat{\Theta}) \quad (4)$$

Note that since $0 < 1 - p(0; \hat{\Theta}) < 1$, the $B\hat{M}D$ obtained from equation (3) is at least as large as that obtained from equation (4).

Various methods (e.g., bootstrap, delta method, and likelihood ratio) exist for calculating the BMDL. Of these, the likelihood-ratio method is recommended as it generally gives better coverage results [12, 14]. Using the likelihood-ratio approach, the BMDL is the minimum BMD such that

$$2[L_{\max} - L(BMD)] \leq \chi^2_{1-(\alpha/2);1} \quad (5)$$

where $L_{\max}$ is the maximum value of $L(\hat{\Theta})$ and $\chi^2_{1-(\alpha/2);1}$ is the 100 $(1 - \frac{\alpha}{2})\%$ percentage point of the χ^2 distribution with 1 degree of freedom.

Many dose–response models exist that can be used to model the risk at a specific dose for quantal data. (For detailed descriptions of some of the popular models see, for example, [6, 15].) Examples of such models include the logistic model (*see Logistic Regression*)

$$p(d) = [1 + \exp(-\alpha - \theta d)]^{-1} \quad (6)$$

and the Weibull model,

$$p(d) = \alpha + (1 - \alpha)[1 - \exp(-\theta d^\alpha)] \quad (7)$$

In many cases, more than one model adequately fits the data at hand. In such cases, the model with best fit should be employed [16]. Besides the adequacy of the model, biological plausibility, consistency between the estimated model and the observed variables, the Akaike’s information criterion (AIC), the magnitude of the difference between the BMD and BMDL are all factors to be considered when choosing the model [8].

In many developmental and reproductive toxicology studies, the binomial model is inappropriate because of the possible correlation of responses between fetuses in the same litter (i.e., litter effect). To incorporate the extra-binomial variation owing to this added litter effect, a generalized binomial model such as the beta binomial is used to model risk [17]. Once

the log-likelihood is maximized, equations (3–5) are used to obtain the BMD and BMDL.

The BMD for Continuous Response Data

When the endpoint of interest is measured on a continuous scale (e.g., altered body weight), it is difficult to define and observe an adverse effect unambiguously [18]. One way to deal with such situations is to consider a continuous response that exceeds a specified cutoff to be abnormal. This dichotomization, in effect, induces a quantal response from continuous data and the methodology outlined above for quantal data can be applied to obtain the BMD/BMDL. Although this is a simple approach, it does not make optimal use of the data. Furthermore, the data may be available only in summary form (e.g., mean response) and such dichotomization cannot be achieved [2]. Another more practical approach is to assume that response, y_{ij} , of the j th subject at dose d_i is normally (or log-normally [19]) distributed, $i = 1, 2, \dots, g; j = 1, 2, \dots, N_i$. Then, under the normal distribution and assuming a constant variance among the g dose groups, the log-likelihood function has the form:

$$L = -\frac{g}{2} \ln(2\pi) - \sum_{i=1}^g \left[\frac{N_i}{2} \ln \sigma^2 + \frac{(N_i - 1)s_i^2}{2\sigma^2} + \frac{N_i(\bar{y}_i - \mu(d_i))^2}{2\sigma^2} \right] \quad (8)$$

where $\mu(d_i)$ is the observed mean for the i th dose group from the assumed model s_i^2 and $\bar{y}_i$ are the usual sample variance and mean, respectively, of the i th dose group. When the variance is not constant among the different dose groups and is allowed to be a power function of the mean i.e., $\sigma_i^2 = \alpha[\mu(d_i)]^\rho$, the log-likelihood takes the form:

$$L = -\sum_{i=1}^g \left[\frac{N_i}{2} \ln \alpha + \frac{N_i \rho}{2} \ln[\mu(d_i)] + H_i \right] \quad (9)$$

where

$$H_i = \frac{A_i}{2\alpha[\mu(d_i)]^\rho} + \frac{B_i}{2\alpha[\mu(d_i)]^{\rho-1}} + \frac{N_i}{2\alpha[\mu(d_i)]^{\rho-2}} \quad (10)$$

with

$$A_i = (N_i - 1)s_i^2 + N_i\bar{y}_i^2 \quad \text{and} \quad B_i = N_i\bar{y}_i \quad (11)$$

For continuous dose–response models, the BMD is defined to be the dose that results in a predefined change in the mean response. The change can be any of the following:

1. An absolute change in the mean response. In this case, the estimated BMD ($\hat{BMD}$) is obtained by solving the equation $|\mu(BMD) - \mu(0)| = R^*$, where R^* is the specified BMR.
2. A change in the mean equal to a specified number of control standard deviations and the $\hat{BMD}$ is attained as the solution to the equation $|\mu(BMD) - \mu(0)| = R^*\hat{\sigma}_0$.
3. A specified fraction of the control group mean and the $\hat{BMD}$ is the solution to the equation $|\mu(BMD) - \mu(0)| = R^*\mu(0)$.
4. A specified value of the mean at the BMD and the $\hat{BMD}$ is the solution to the equation $\mu(BMD) = R^*$.
5. A change equal to a specified fraction of the range of the responses and the $\hat{BMD}$ is the solution to the equation $\frac{\mu(BMD) - \mu(0)}{\mu_{\max} - \mu(0)} = R^*$. Here again, the BMDL can be calculated by appealing to equation (5).

As in the quantal case, several statistical dose–response models exist to model risk for continuous endpoints (see, for example [6, 15]).

More recently, Pan *et al.* devised simultaneous confidence bounds that have applications in multiple inferences for low-dose risk estimation [20]. The developed methodology can be used to construct simultaneous, one-sided, upper confidence limits on risk for quantal or continuous endpoints. By inverting the upper confidence limits on risk, BMDLs can be obtained for any finite number of prespecified BMRs. Throughout the effort, valid $100(1 - \alpha)\%$ inferences can be made by the underlying simultaneity of the method. The simultaneous approach was later applied to quantal and continuous data [7, 21]. Nitcheva *et al.* adjust the simultaneous limits for multiplicity by applying a Bonferroni adjustment for quantal data and Wu *et al.* adjust for the multiplicity problem for continuous response data [13, 22]. Another recent development is the application of the BMD method *via* bootstrapping to longitudinal data arising in neurotoxicity studies [23].

Benzene

The intent of this article is to familiarize the reader with the background of regulatory risk assessments of benzene and the epidemiological, exposure, medical, and biochemical issues of this compound, which are important in the risk assessment process, are in many instances unresolved. Benzene is possibly the most highly regulated, highly studied, and recognized human carcinogen in the history of toxicology. This classification has been formalized by organizations such as IARC (International Agency for Research on Cancer), the USEPA (United States Environmental Protection Agency), and the EU (European Union). It is virtually ubiquitous in most terrestrial environments [1] due to its origin in both anthropogenic sources such as motor gasoline as well as its exhaust and cigarette smoke, and naturally occurring sources such as wildfires and volcanism.

Physical/Chemical Properties

Benzene, molecular formula C_6H_6 and molecular weight 78.1, is the simplest of the aromatic hydrocarbons. Benzene is quite volatile with a boiling point of $80.1^\circ C$ and vapor pressure at $26^\circ C$ of 100 mmHg. Liquid benzene in the environment or workplace will evaporate readily, and, therefore, inhalation is a major potential exposure pathway. Benzene is described as having a pleasant, sweet aromatic odor. Although there is a wide range of reported values, the most commonly endorsed odor threshold is 1.5–8 ppm [2]. The liquid is lighter than water (0.874 g ml^{-1} at 25°) and is somewhat water soluble (1.8 g l^{-1}) resulting in its presence in surface or groundwater in contact with benzene-containing products. This has been most commonly seen as the presence of benzene-containing groundwater around leaking underground gasoline tanks. With a flash point of $-11.1^\circ C$ and flammability limits of 1.5–8.0% in air by volume, benzene is classified as a highly flammable substance.

Evolution of the Understanding of Benzene Toxicity

The potential for chronic toxicity of benzene was reported as early as the 1890s [3]. Exposure to large amounts of benzene was known to result in aplastic

anemia and often death. During the first half of the twentieth century, more cases of hematotoxicity following occupational benzene exposure were reported. Typical findings of that period were documented in the publication of a series of case studies by Hamilton [4]. The potential for health impacts from benzene exposure became even more well known with the publication of an extended case series of Turkish shoe and leather workers in the 1970s [5]. Aksoy, a Turkish physician, described hematotoxicity in peripheral blood of these individuals as well as described cases of leukemias. Owing to the presence of benzene in glues used by the workers, benzene concentrations in the workplace were as high as 600 ppm. Vigliani described a series of Italian printers exposed to high concentrations of benzene in the rotogravure industry, who developed hematologic disease including various leukemias [6]. Benzene concentrations were characterized as high but no quantitative measurements were reported, and the authors, therefore, did not attempt to develop a quantitative relationship between exposure and disease.

The recognition that exposure to benzene could be related to the subsequent development of one or more forms of hematopoietic malignancy was established with the publication of a retrospective cohort mortality study of workers employed by Goodyear Corporation in the manufacture of sheets of rubber hydrochloride film known as *Pliofilm* [7]. This cohort has since become referred to informally as the *Pliofilm cohort*. Pliofilm was used extensively in waterproofing and protective coating applications, from the 1930s to the 1960s or early 1970s. Although reliable air monitoring of benzene was largely nonexistent until the 1960s, this cohort has the advantage of no confounding exposures to other hydrocarbon solvents. The cohort has been updated in 1988 and again in 2002. The authors performed a conditional logistic regression analysis in which they related stratified exposures to benzene to Standardized Mortality Ratios (SMRs) for “all leukemias” in order to develop a dose–response for benzene-related leukemogenesis [8].

Subsequent to the publication of the initial Pliofilm cohort study, numerous publications the link between benzene exposure and acute forms of myeloid leukemia was solidified. However, many authors felt that lymphoid forms of hematopoietic malignancy could not be excluded. In 1997 the US National Cancer Institute in collaboration with the

Chinese Academy of Preventive Medicine published the results of a cohort study of over 70 000 Chinese workers in approximately 80 industries who were judged to be exposed to benzene in the workplace [9]. These authors reported an association between benzene exposure and increase in acute myelogenous leukemia (AML) as well as the unexpected association of benzene exposure with an increase in non-Hodgkin lymphoma (NHL). Although other authors had previously reported possible links between benzene and NHL, this was the first study that reported that NHL is related to quantitative estimates of benzene exposure rather than unspecified concentrations of benzene in hydrocarbon solvents or occupation in certain jobs considered to involve benzene exposure.

Since 1980, the Australian petroleum industry has sponsored a prospective cohort study of petroleum refinery and distribution workers in Australia. Referred to as the Health Watch study, it has been conducted by several Australian universities. Similar to US and EU petroleum cohorts, exposures have been low and the updates of the cohort mortality data have not reported consistent increases in any form of leukemia. A nested case-control study published by Glass *et al.* [10] and the update of the cohort in 2000 reported a statistically significant increase in AML after cumulative exposures of less than 8-ppm years. This cumulative exposure is much lower than the range of threshold estimates of 50–200-ppm years estimated from the updated Pliofilm cohort. A significant increase in AML at these low levels is not supported by data from the most recent update [11].

The current consensus seems to be that benzene can reliably be considered to have a causative relationship to acute nonlymphocytic leukemia (ANLL). There is considerable dispute about the relationship between benzene and NHL. This is clouded by the fact that NHL is a composite term for over 20 distinct forms of lymphoid malignancies [12].

Animal Data

Unlike many other carcinogens, there is no accepted animal model for benzene-induced leukemia. Lifetime oncogenicity studies of benzene administered by gavage or by inhalation in mice and rats have shown the presence of solid tumors in tissues such as preputial gland in male mice, Zymbal gland in

rats, and liver tumors in female mice. Hematopoietic malignancies have been observed in rats exposed to benzene, but the hematologic changes seen in rodents have not been directly equated with human leukemias (*see Cancer Risk Evaluation from Animal Studies*).

Although animal data is not currently used as a basis for quantitative risk assessment of benzene, studies on rodents and other species such as nonhuman primates have provided useful information about the pharmacokinetics and metabolism of benzene that can be applied to humans. Although a laboratory animal model of ANLL has not been discovered, the interactions of benzene and its metabolites with genetic material and their effects at the biochemical level on systems such as DNA replication and regulation of hematopoiesis have provided important insights into the potential mechanisms of benzene-induced leukemogenesis in humans [13].

Metabolism

It is accepted that benzene must be metabolized to result in hematotoxicity. The initial step in benzene metabolism is the formation of benzene oxide *via* metabolism by cytochrome P-450 IIE1 (CYP1IE1). This reactive intermediate may rearrange to form phenol (the major pathway) or may undergo ring opening leading to muconaldehyde, an alkylating agent, and ultimately to muconic acid excreted in the urine (a minor pathway). A third minor reaction of benzene oxide occurs with glutathione to form *S*-phenyl glutathione. A second hydroxylation on the phenol pathway generates either catechol or hydroquinone. Hydroquinone can oxidize to benzoquinone, a very strong alkylating agent and generator of chemically reactive oxygen species. Although there has been controversy in the past about the role of the muconic acid pathway, the oxidative route to hydroquinone is generally thought to be the toxicologically relevant pathway [2].

Understanding of the metabolism of benzene has a significant value in the risk assessment process. The initial urinary phenol test recommended by American Conference of Governmental and Industrial Hygienists (ACGIH) and Occupational Safety and Health Agency (OSHA) has been replaced by immunological assays of urinary *S*-phenyl mercapturic acid, a metabolite of *S*-phenyl glutathione. This can be as

much as 3 orders of magnitude more sensitive than former assays and there are no known dietary confounders. Identification of the enzymes involved in metabolism of benzene and in detoxication of its metabolites has led to the discovery of genetic polymorphisms in these enzymes, which may help to explain interindividual variation in benzene hematotoxicity. These polymorphisms have been related to the risk of hematopoietic toxicity after chronic exposures to high concentrations of benzene [14]. The importance of these polymorphisms to potential toxicity at much lower concentrations such as US and EU occupational standards or at urban ambient concentrations is not known.

Regulatory History

Prior to the formation of the ACGIH in 1946, benzene had been the subject of occupational exposure recommendations from various sources. A typical recommendation not to exceed 100 ppm was based upon the known hematotoxicity of benzene including aplastic anemia. This 100 ppm recommendation as an 8-h time-weighted average (TWA) was adopted by ACGIH as its first threshold limit value (TLV) for benzene. Over the years, as more information became available, the TLV was revised downward with new values of 50, 48, 35, 25, and 10 ppm between 1948 and 1970.

OSHA

Reacting to the reports of benzene-associated leukemias by Aksoy and Vigliani, and the results of the Pliofilm study, the US OSHA in 1978 promulgated an emergency standard for benzene of 1 ppm as an 8-h TWA. This was supported by a new quantitative risk assessment of the Pliofilm cohort by Crump and Allen [15]. The OSHA benzene risk assessment by Crump and Allen [15] was based upon data from the Pliofilm cohort. The authors attempted to refine the exposure analysis used by National Institute for Occupational Safety and Health (NIOSH) by assuming that benzene exposure in the workplace would have changed in parallel with changing occupational exposure recommendations. They then worked backward from typical exposures of the 1970s (when the TLV ranged between 10 and 25 ppm) to the 100 ppm recommendation during

the earliest years of the cohort. These estimated exposures were somewhat higher than the values assumed by the NIOSH authors. Crump and Allen followed the practice at that time of basing their risk assessment on mortality from all leukemias. These results were used by OSHA to set a final 8-h TWA standard for benzene of 1 ppm in 1987 [16].

USEPA

USEPA also calculated a unit risk factor for benzene in a risk assessment that was published in USEPA [17]. This estimate was performed by Crump, also the author of the OSHA risk assessment, and the total leukemia mortality outcome of the Pliofilm cohort was used as the primary basis of the estimate. In addition, two other studies of smaller chemical industry cohorts were factored into the risk estimate [18, 19]. The cancer unit risk value estimated by Crump for EPA was $0.026 \text{ mg}^{-1} \text{ M}^{-3}$. This has been updated from a single point estimate to a range of unit risk estimates from 2.6×10^{-6} to $7.8 \times 10^{-6} \mu\text{g}^{-1} \text{ M}^{-3}$ [20].

IARC

Although not a regulatory agency, the IARC is widely regarded as authoritative for classifying potential carcinogenic hazards to humans. In volume 29 of its monograph series, IARC reviewed the available data on benzene and listed it as Group I, a known human carcinogen [21].

ACGIH in the 1990s

Although ACGIH TLVs are recommendations and do not carry the force of law, they are influential in the standard setting processes of many regulatory bodies. The mortality data of the Pliofilm cohort was updated in 1988 by NIOSH. In 1990 the ACGIH proposed a reduction of the then current TLV of 10–0.1 ppm. In response to this proposal the updated cohort data was used by Paxton *et al.* [22] and Crump [23] as the basis for new risk estimates. Paxton *et al.*, using a variant of logistic regression compared risk estimates based upon exposures used by NIOSH and Crump. On the basis of the more conservative exposure estimates of Rinsky, Paxton determined that

a threshold for ANLL occurred at exposures below 50-ppm-years. The Crump analysis compared risk estimates for exposures estimated by Rinsky *et al.* [8], Crump and Allen [15], and Paustenbach *et al.* [24]. The latter estimates were based on job-specific information and interviews with surviving workers, and they incorporated potential peak exposures for some job tasks. Crump [23] also compared results from nonlinear as well as linear dose-response models. Finally in 1996 the ACGIH set a new recommendation of a 0.5-ppm TLV with a 15-min short-term exposure limit (STEL) of 2.5 ppm [25].

Europe and Other Nations

The current occupational standard for benzene is 1 ppm in the EU [26], Korea [27], and Germany [28]. In the People's Republic of China, the occupational standard has been recently reduced from 14 to 5 ppm [29]. With the exception of the Chinese occupational standard, the other national standards are all based in some way or strongly consider the results of the Pliofilm cohort.

Unresolved Issues

At present significant uncertainties remain before the risks of benzene-induced hematopoietic disease can be fully and accurately understood. The primary uncertainties are the identification of those hematopoietic malignancies that are causally related to benzene exposure and the nature of the dose-response relationship between benzene exposure and those malignancies. The latter issue includes the question of whether or not a true or apparent threshold exists for benzene-induced leukemias or lymphomas.

Cell Type

At present there is consensus that benzene can induce ANLL. Other cell types of hematological malignancies including lymphocytic leukemias and lymphomas have been alleged as being causally linked to benzene; however, the support for these cell types is weaker and multiple studies have reported inconsistent results. Myelodysplastic syndrome is

closely associated with some forms of ANLL and is often considered as potentially due to benzene exposure. Current regulatory risk assessments are based upon the assumption that benzene may be related to all or most leukemia cell types.

Dose-Response and Threshold

The mechanism by which benzene exposure results in hematologic malignancies is not currently understood, but there is a consensus that it must involve a multistep process that involves both genetic alterations resulting in clonal abnormalities and non-genetic interference with the normal regulation of hematopoiesis [30, 31]. This epigenetic dysregulation may be at the level of differentiation and/or proliferation of one or more cell types during hematopoiesis. The specifics of the mechanism have important ramifications for risk assessment in that they can define the shape of the dose-response relationship (*see Dose-Response Analysis*) between benzene exposure and leukemia response. The existence of a real or effective threshold for induction of leukemia will depend upon the specifics of the leukemogenic mechanism.

Biomonitoring – Breath Benzene, Phenol, S-Phenylmercapturic Acid (SPMA)

A significant research effort is under way to identify biomarkers that could be used to extend the range of the dose-response relationship for benzene-induced leukemogenesis. The current problem in this field is separating those phenomena that are biomarkers of effect (and causally related to induction of leukemia) from those that are merely biomarkers of exposure. The latter may be useful for exposure monitoring but bear no causal relationship to the induction of disease.

Summary

Benzene-induced leukemogenesis lies at the intersection of medicine, industrial hygiene, toxicology, and epidemiology. All of these disciplines have critical contributions to make in a risk assessment of benzene-induced leukemogenesis. At this time all of these disciplines suffer from critical uncertainties that

need to be resolved for a complete understanding of this phenomenon.

PATRICK BEATTY

Bioequivalence

Two drug formulations are bioequivalent if their absorption characteristics are closely similar. The most important characteristics are the extent and rate of absorption, which together define the bioavailability of a drug formulation. Thus, *bioequivalence* is the comparable bioavailability of drug formulations.

Kinetic Measures of Bioavailability

Measures After a Single Drug Administration

When drugs are not administered directly into the systemic circulation, as in the case of oral intake, at least a fraction of the dose should first be absorbed. As a result, the concentration in blood and plasma initially rises (Figure 1). The drug is then distributed to various tissues and also starts being eliminated from the body. Consequently, after reaching a peak, the concentration declines (Figure 1).

The principal measures (metrics) characterizing bioavailability, and therefore bioequivalence, are the area under the curve (AUC), contrasting concentration with time, and the maximum concentration, $C_{\max}$, which is observed at the time of $T_{\max}$ (Figure 1). AUC is a measure of the extent of absorption. AUC rises as the absorbed fraction of drug dose, i.e. the amount reaching the circulation, increases.

$C_{\max}$ is the most widely used index for the evaluation of absorption rates, especially in comparative studies. $C_{\max}$ actually reflects several processes of drug disposition, including the extent of absorption. However, if, in two drug formulations, all processes except the absorption rate have the same magnitudes (often a good assumption, at least approximately), then differences of $C_{\max}$ values indeed indicate deviations between absorption rates. A higher $C_{\max}$ signals (everything else being equal) a faster absorption rate.

$T_{\max}$ is also determined by various processes of drug disposition. Consequently, contrasts in $T_{\max}$ reflect deviations between absorption rates only if magnitudes characterizing other processes of drug disposition remain the same. Under this condition, a smaller $T_{\max}$ indicates a higher absorption rate.

AUC, $C_{\max}$, and $T_{\max}$ are often referred to as model-free measures of bioavailability because they

are determined independently of assumed pharmacokinetic models.

Measures After Repeated Drug Administrations

Following repeated administrations of a given drug dose, D , the concentration in plasma and blood eventually reaches a quasi-steady state. In this condition, after each administration of the drug, the concentration first rises, passes through a maximum, $C_{\max}$, and then declines toward a minimum or so-called trough value, $C_{\min}$. The time profile of concentrations is illustrated in Figure 2.

The kinetic measures of bioavailability parallel, in the steady state, the metrics noted for single administration. AUC is again an index of the extent of absorption. However, it is evaluated after repeated administrations by measuring the area recorded during the time interval between two dosings (the dosing or maintenance interval, T). This AUC is numerically identical to the value obtained following a single drug administration, provided that the drug exhibits first-order kinetics (i.e. the rate of change in the concentration is proportional to the concentration) and that this is identical under the two conditions.

Absorption rates are usually less important when considering repeated drug administrations than after a single drug administration. Nevertheless, $C_{\max}$ is still important, especially as an index of drug safety; unusually high concentrations could indicate a danger of toxicity.

Additional measures of bioavailability are considered later.

Assessment of Bioequivalence

Several statisticians have made distinguished contributions since the early 1970s toward developing the methodology for the assessment of bioequivalence. They notably include Carl M. Metzler and Wilfred J. Westlake and also, among others, Sharon Anderson, Walter W. Hauck, Jochen Mau, & Bruce E. Rodda. Chow and Liu [1] reviewed the statistical aspects of the evaluation of bioequivalence.

Procedures that are applied most widely at present are briefly described. Sauter *et al.* [2] illustrated examples for detailed calculations evaluating bioequivalence following single drug administrations and in the steady state.

Figure 1 Time course of plasma concentration following a single oral administration of a drug

Figure 2 Time course of plasma concentration following repeated oral administrations of a drug

Two One-Sided Tests Procedure

The two one-sided tests procedure is nowadays widely applied for the assessment of bioequivalence. Yee [3] presented some features of the approach, and Schuirmann [4] elaborated them. The goal is to compare the mean kinetic responses of a reference (R) formulation and an investigated test (T) drug product. The null hypothesis to be tested is that of bioinequivalence. The test is subdivided into two one-sided problems. They assume bioinequivalence if the difference between the means is either less than or equal to a regulatory criterion θ_1 or (/and) larger than or equal to another regulatory value θ_2 :

$$H_{01} : \mu_T - \mu_R \leq \theta_1; \quad H_{02} : \mu_T - \mu_R \geq \theta_2 \quad (1)$$

The null hypothesis could be rejected in favor of an alternative hypothesis indicating bioequivalence:

$$H_a : \theta_1 < \mu_T - \mu_R < \theta_2 \quad (2)$$

If both null hypotheses are true, their evaluation at the $\alpha/2$ significance level indicates a consumer risk on both sides with this probability.

The two null hypotheses are, in practice, assessed by the use of confidence intervals. Various approaches have been proposed. The application of the shortest interval at the α level [4, 5] has been widely adopted. It yields, at a given significance level (and consumer risk), the highest power, i.e. the smallest risk for producers when the two formulations are in fact bioequivalent [6].

Implementation of the Two One-Sided Tests Procedure

Most kinetic quantities are considered to have multiplicative character (their multiplication and division – e.g. whether their magnitudes should be raised or lowered by a factor of 2 or 10 – appear to be relevant). Correspondingly, their errors are also thought to be multiplicative and not additive [6, 7]. Therefore, they are typically evaluated and compared in their logarithmic form. Consequently, μ_T and μ_R are estimated after the logarithmic transformation of the investigated quantity, e.g. from $\log AUC$ or $\log C_{max}$. The regulatory limits are usually considered to be symmetrical. Consequently, $\theta_2 = -\theta_1$ in the logarithmic scale. Times of the observations are not regarded to have multiplicative character. Moreover, they are recorded only at discrete sampling points. Therefore, T_{max} is generally not transformed and not assessed with regulatory limits. $\alpha = 0.10$ is widely applied.

The bioequivalence of two drug formulations is evaluated generally in two-period, two-sequence, crossover trials. The kinetic responses (e.g. AUC) estimated for both formulations are contrasted in each subject. From the difference of individual logarithmic responses, their average and its 90% confidence interval are calculated. Bioequivalence is declared if the limits are in the regulatory range, between θ_1 and θ_2 . The values of θ_1 and θ_2 are considered below.

Distribution-Free Procedure

Hauschke *et al.* [8] described a nonparametric procedure that, in its implementation of the two-sided hypotheses, took into account the structure of two-period, two-sequence, crossover studies. The kinetic parameters recorded with the test and reference

formulations (X_T and X_R) are contrasted within each individual:

$$X_i = X_{Ti} - X_{Ri}, \quad i = 1, \dots, n \quad (3)$$

Let the number of subjects in the two sequences of drug administration be n_1 and n_2 , with $n_1 + n_2 = n$. A total of $n_1 n_2$ differences in the two sequences,

$$X_{j1} - X_{j^*2}, \quad j = 1, \dots, n_1, j^* = 1, \dots, n_2 \quad (4)$$

are formed and sorted by magnitude. The median of the pairwise differences is a Hodges–Lehmann point estimator of $2(\mu_T - \mu_R)$. Ninety percent confidence limits are also obtained from the ranked differences.

Rapidly Evolving Issues

Various issues remain unresolved about the evaluation of bioequivalence. Two important topics are discussed that have particular relevance in biostatistics. They are developing rapidly and, therefore, their resolution in the near future is anticipated.

Individual Bioequivalence

The criteria discussed so far for the acceptance of bioequivalence involve the comparison of average kinetic parameters. Thus, the resulting similarity of two drug formulations is referred to as *average bioequivalence*. It ensures that the efficacy and safety of the new drug product is, on average, similar to that of the reference formulation. It is recognized that the efficacy and safety of the reference product was thoroughly evaluated during its development.

Average bioequivalence ensures that an individual who had not been exposed to either drug formulation would have generally similar responses to both products. Thereby, the *prescribability* of the test formulation is demonstrated. When, as often happens, patients are already receiving the reference product, then its substitution by the test formulation is contemplated. The issue is, therefore, the *switchability* from one formulation to another [9]. Thus, the similarity of responses and kinetic parameters *within* individuals, and therefore *individual bioequivalence*, becomes important.

To assess individual bioequivalence, the intrasubject variances of the reference and test products (σ_{WR}^2 and σ_{WT}^2) need to be estimated. This can be

accomplished if three- or four-period crossover trials are conducted. This design also enables the estimation of the subject $\times$ formulation interaction (σ_{SF}^2), which can be a major source of lack of individual bioequivalence.

The procedures proposed by several authors for the evaluation of individual bioequivalence can be separated into two principal categories [10, 11]. Probability-based approaches assume that deviations between individual kinetic parameters for the two formulations (X_R and X_T) would remain within a specified range and have a probability $\Pr(|X_T - X_R| \leq r)$, which should be sufficiently high. Moment-based procedures consider the second moment of $X_T - X_R$. A measure would extend that given for average bioequivalence, equation (2), by including terms for σ_{SF}^2 , σ_{WR}^2 , and σ_{WT}^2 . A one-sided criterion is generally

$$(\mu_T - \mu_R)^2 + \delta \sigma_{SF}^2 + \phi \sigma_{WR}^2 + \gamma \sigma_{WT}^2 < \theta_1 \quad (5)$$

The regulatory criterion θ_1 as well as the coefficients δ , ϕ , and η will have to be determined. For instance, it has been suggested that $\delta = \phi = 1$ and $\gamma = -1$ [12]. Sheiner [13] recommended $\delta = \gamma = 1$ and $\phi = 0$. Other values have also been proposed for the coefficients.

An unscaled measure such as that given above can be divided by a combination of σ_{WR}^2 and σ_{WT}^2 . The resulting scaled bioequivalence criterion differs intrinsically from its unscaled counterpart. It is anticipated that scaled comparisons will be particularly useful for assessing the bioequivalence of drugs that exhibit high intraindividual variability; the analysis of their equivalence is very difficult and, at times, even impossible by applying the methodology of average bioequivalence.

Similar conclusions can be drawn for probability-based measures of individual bioequivalence since they have close relationships to the corresponding moment-based measures [14, 15].

Kinetic Measures for the Evaluation of Bioequivalence

There is general agreement that AUCs measure the extent of absorption well, and that the application of the two one-sided tests procedure to relative AUCs appropriately evaluates the equivalence of extents of absorption of two drug formulations. Consequently, two drug products are considered to be bioequivalent

by this criterion if the 90% confidence interval around the geometric average of individual AUC ratios is between 0.80 and 1.25 [16].

A similar consensus has not been reached about metrics evaluating the equivalence of absorption rates. $C_{\max}$ is used most frequently. The various regulatory agencies apply differing criteria to indicate equivalence. For example, the Food and Drug Administration in the United States has requirements for $C_{\max}$ s that parallel those for AUCs: the 90% confidence interval around the geometric average of individual $C_{\max}$ ratios should be between 0.80 and 1.25. The European Union recognizes that $C_{\max}$ is determined generally with larger variation than AUC. Therefore, its condition for the equivalence of $C_{\max}$ s is less demanding: the stated 90% confidence limits should be between 0.70 and 1.43. Canadian regulatory requirements do not invoke confidence limits and are, therefore, even less demanding: it is sufficient for the declaration of bioequivalence if the geometric average of individual $C_{\max}$ ratios is between 0.80 and 1.25.

In addition to the diversity of regulatory criteria, questions have been raised about the usefulness of $C_{\max}$ for determining the equivalence of absorption rates. $C_{\max}$ notably reflects various kinetic quantities and processes, including the extent of absorption. Moreover, $C_{\max}$ responds to changes in absorption rates very insensitively, particularly in the steady state. The statistical properties of the metric are also unfavorable. Interestingly, its variation in the steady state can be higher or lower than that observed after a single drug administration, depending on the contributions of various sources of variation [17].

Therefore, reasonably, alternative measures have been suggested for assessing the equivalence of absorption rates after a single drug administration. They include, following a single drug administration, $C_{\max}/\text{AUC}$, AUC measured until the peak of the reference formulation (partial AUC), and the intercept obtained by linear extrapolation from the ratios of concentrations of the two formulations measured in the early stage of a study [18–20].

After repeated drug administrations, in the steady state, the most frequently applied metric is, in addition to $C_{\max}$, the peak – trough fluctuation, PTF; $\text{PTF} = (C_{\max} - C_{\min})/C_{\text{ave}}$, where C_{ave} and $C_{\min}$ are the average and minimum concentrations, respectively, during a dosing interval [21]. Other measures include the Swing $[(C_{\max} - C_{\min})/(C_{\min})]$, the AUC

above C_{ave} normalized by the total AUC within a dosing interval (AUCF), and the duration (T75) of the concentration peak at the level of 3/4 of its adjusted height, i.e. at $0.75C_{\max} + 0.25C_{\min}$ (see Figure 2).

Little is known, at present, about the properties of these metrics, which are being explored extensively by several investigators.

Blinding

The validity of any research experiment or study is threatened by bias. Bias may arise, for example, when the patient or the person administering the treatment knows which treatment is being allocated [1]. This type of bias is known as *ascertainment bias* or *information bias* [2]. In order to reduce bias, it is necessary to ensure that the patients and the investigators are blind to (do not know) which treatment is allocated to whom. The purpose of blinding is to prevent conscious and unconscious bias associated with the expectations of patients and investigators.

Different types of bias can be prevented or reduced by blinding. For example, blinding of patients and health care providers helps prevent *performance bias* that may occur if biased supplemental care or treatment (sometimes called *cointervention*) is provided preferentially to one of the treatment groups (e.g., the placebo group) [3]. One can also blind other study personnel such as data collectors, outcome assessors, and/or data analysts. This helps to reduce the *detection bias* that arises when the knowledge about the assignment of patients influences the assessment of outcome.

The terms *single*, *double*, and *triple* blinding are often used to communicate the blinding status of the persons involved in a study. The terminology *double-blinded* usually means that neither the participants nor the investigators responsible for monitoring the participants know which intervention each participant is receiving. In a *single-blinded* study, either the participants or the trial investigators/evaluators remain unaware of intervention assignments throughout the trial. *Triple blind* usually means a double-blind trial that also maintains a blind data analysis [1].

Sometimes the nature of the study precludes blinding of participants and/or health care providers [1, 4]. Such studies include those involving a surgical procedure, comparison of medical devices, changes in lifestyle (e.g., eating habits, exercise, and cigarette smoking), and learning techniques. However, even when the study participants and those administering treatment cannot be blinded, blinding of outcome assessment could still be possible and helps prevent detection bias [3, 5].

Reporting the blinding status of the persons involved in a research study and the blinding methodology is necessary in order for the reader to be able to judge the validity of the study [4]. However, the blinding efforts are often poorly reported [5–7]. This is partially due to the ambiguity in the blinding terminology: the terms such as *single*-, *double*-, and *triple-blinded* are not well defined and vary from textbook to textbook and from physician to physician [2, 5, 6]. Therefore, stating that a study is double-blinded is not enough: the authors should explicitly state who were blinded and how they were blinded, and provide information about the blinding mechanism (e.g., caplets, tablets, etc.) and similarity of the treatment characteristics (appearance, taste, and administration) [2, 6, 8].

While all researchers agree that the blinding methodology should be clearly reported, there has been a considerable debate about the value of assessing the success of blinding at the end of the trials. Fergusson *et al.* [7] argue that researchers should assess and report the efficacy of blinding, while others argue that asking the patients or their clinicians at the end of a trial which drug they thought they were taking confounds failures in blinding with successes in pretrial hunches about treatment efficacy or adverse events [9]. For example, if the treatment is highly effective, the patients might correctly guess which group they were assigned to. In this case, the end of study test for blindness would lead to the incorrect conclusion that blinding was unsuccessful. Sackett [9] recommends rigorous testing for blindness before the trial begins, but not during the trial and never at the end of the trial.

In conclusion, the objective of blinding is to contribute to the elimination of bias that may be introduced intentionally or unintentionally by the various individuals involved in a research study. Careful reporting of the blinding status of all the individuals involved in a research study and the blinding mechanisms helps the reader to judge the validity of the study and ensures the credibility of its results.

Bonus–Malus Systems

When the actuary sets a price for an insurance policy, he has to analyze many factors, namely

- the expected loss of the policy;
- the expenses associated with writing the policy and settling the claims;
- the investment returns owing to the inversion of the business cycle;
- the capital costs.

Although all these elements are important, we concentrate here on the determination of the so-called pure premium, i.e., the expectation of the losses aggregated over a 1-year period (typically insurance policies are written for a 1-year period). The other three elements are briefly described.

Administrative expenses are incurred for writing new policies and renewing existing policies. They correspond to the salaries of the employees as well as the cost of marketing efforts to get new business. Administrative expenses are also incurred for settling the claims. They essentially correspond to the salaries of the employees as well as costs to defray experts and lawyers. These expenses are random, as it is not possible to forecast exactly what the costs will be in the future.

In motor insurance, when there are claims with bodily injuries, it often takes years before claims are completely settled. For example, claims with bodily injuries may take more than 15 years to be settled in Belgium. Because the premium is paid up front, but the claims are settled later (often years later), the insurer benefits from the investment returns on the accumulated premiums. This aspect may be taken into account to give rebates on the expected costs to the policyholders.

On the other hand, we should not forget the shareholders who provide capital to the insurance company. That capital is vital to attract policyholders. Indeed, policyholders want to make (almost) sure that the insurer will be able to compensate them (or the third parties) when there is a claim. Should the accumulated premiums be insufficient (owing to the stochastic process governing the claims generation, or because of the actuary used a wrong model), the shortfall is paid by using the capital provided by the shareholders. Obviously, shareholders want to be

remunerated for providing capital at risk and this translates into a margin that should be charged over and above the pure premium.

Denoting the annual number of losses by N , and the cost of the i th loss by X_i , we can see that the annual aggregate loss is given by $S = X_1 + \dots + X_N$. Under the assumption that the X_i s are independent and identically distributed, and independent of N , the pure premium is given by $\mathbb{E}S = \mathbb{E}N\mathbb{E}X_1$.

In automobile insurance, the number of claims is known to vary among policyholders more than the severity of the claims does. We will now focus this discussion on the number of claims filed by a policyholder.

The determination of $\mathbb{E}N$ (actually we have a model for the distribution of N) is done in two steps:

1. An *a priori* tariff is applied, based on the known characteristics of the policyholder. Declining the policy may be an option of the tariff. Imposing deductibles and/or limits on the financial compensations may also be an option in the *a priori* tariff.
2. An *a posteriori* tariff is applied after the policyholder has been observed for some insurance periods leading to bonuses or maluses. Cancellation of the policy is actually part of the *a posteriori* tariff of the insurance company.

In this chapter, we briefly comment on a particular type of *a posteriori* tarification, namely, bonus–malus systems.

An *a posteriori* tariff is made necessary when it is not possible to discover all the characteristics of the policyholders such that the *a priori* tariff is missing important elements.

We discuss bonus–malus systems in the framework of motor third party liability insurance because the claim frequency is relatively large for that kind of insurance. Fire policies have much lower claim frequencies (and also less hidden characteristics), making the use of bonus–malus systems less applicable.

Bonus–malus systems have been comprehensively studied by [1], with an update in [2]. A modern treatment of the subject is provided by [3], including a detailed list of references.

The rest of this chapter is organized as follows. The Section titled “Poisson Regression” presents the *a priori* segmentation in a Poisson regression framework. The section titled “Mixed Poisson Regression”

introduces a random effect in the Poisson model to account for heterogeneity. Bayesian updates are deduced in the section titled “Bayesian Analysis”. The section titled “Bonus–Malus Scales” discusses practical bonus–malus scales and introduces their mathematical treatment. Bonus hunger, moral hazard, and signal theory are briefly discussed in the final section.

Poisson Regression

In motor insurance, one usually uses the following covariates in order to categorize the policyholders:

- age, sex, profession, civil status, etc. of the driver;
- type of car, color, power, etc.;
- type (length, deductible, comprehensive cover, etc.) of the contract.

All these covariates allow the classification of the policyholders into relatively homogeneous classes. This is usually done through Poisson regressions. We therefore assume that the number of claims filed by the i th policyholder is Poisson distributed, $N_i \sim Po(\lambda_i)$ with expected frequency $\lambda_i = d_i \exp(score_i)$ where

- d_i denotes the risk exposure of policyholder i (i.e., the time during which the policy is in force);
- $score_i$ is the score of policyholder i modeled by a linear regression: $score_i = \beta_0 + \sum_{j=1}^p \beta_j x_{ij}$;
- $(x_{i1}, \dots, x_{ip})$ denotes the vector of covariates.

The score allows to rank policyholders and the exponential link ensures that the annual frequency will be positive.

The β parameters are easily estimated by standard maximum likelihood techniques.

We assume that, after a statistical analysis of the portfolio, the actuary has m *a priori* classes of drivers, having expected frequency λ_k , $k = 1, \dots, m$.

In the section titled “Bayesian Analysis”, we allow the d_i and $score_i$ to vary with time.

Mixed Poisson Regression

A Poisson model implies equidispersion: $\mathbb{E}[N_i] = \mathbb{V}[N_i]$. However empirical analyses show that there remains some heterogeneity within the classes. This is owing to the nonobservable effects, e.g., usage

of drugs or alcoholic drinks, knowledge of highway code, aggressiveness, etc. Some policyholders with characteristics x_i may have a frequency larger or smaller than λ_i . This is typically modeled by introducing a random effect in the Poisson regression: $N_i | \Theta = \theta \sim Po(\lambda_i \theta)$ such that $\mathbb{E}\Theta = 1$, i.e., we find on average the observed frequency $\mathbb{E}N_i = \lambda_i \mathbb{E}\Theta = \lambda_i$. This mixed Poisson regression model induces overdispersion, $\mathbb{V}[N_i] = \lambda_i + \lambda_i^2 \mathbb{V}[\Theta] \geq \mathbb{E}[N_i] = \lambda_i$, which is observed on empirical data sets.

In other words, the premium for each policyholder in each risk class is an average. The policies are affected by the hidden features modeled by the random effect Θ . The latter is revealed by the claims of the policyholders. Using that information, the conditional distribution of Θ is modified, implying an adaptation of the premium. This justifies the use of a *posteriori* rating schemes, as described in the section titled “Bayesian Analysis”.

Mostly for mathematical ease, the random effect is modeled by a gamma distribution, $\Theta \sim \text{Gam}(a, a)$:

$$f_{\Theta}(\theta) = \frac{1}{\Gamma(a)} a^a \theta^{a-1} \exp(-a\theta), \quad \theta > 0 \quad (1)$$

Then it is possible to show that the unconditional distribution of N_i is negative binomial:

$$\mathbb{P}[N_i = k] = \binom{a+k-1}{k} \left(\frac{\lambda_i}{a+\lambda_i} \right)^k \left(\frac{a}{a+\lambda_i} \right)^a, \quad k = 0, 1, \dots \quad (2)$$

Here again, the β parameters, as well as the a parameter are easily estimated by standard maximum likelihood techniques.

Note that other models are possible for the random effect. Inverse Gaussian or lognormal distributions are suitable alternatives. However, the mathematics becomes much simpler with the gamma distribution.

Bayesian Analysis

Assume now that we observe a policy for T periods with length $d_{i1}, \dots, d_{iT}$, i.e., the number of claims $N_{i1}, \dots, N_{iT}$ have been filed and the past *a priori* annual frequencies $\lambda_{i1}, \dots, \lambda_{iT}$ have been recorded. λ_{it} is computed as follows:

$$\lambda_{it} = d_{it} \exp(score_{it}), \quad t = 1, \dots, T \quad (3)$$

where

$$score_{it} = \beta_0 + \sum_{j=1}^p \beta_j x_{ij}(t), \quad t = 1, \dots, T \quad (4)$$

where the covariate $x_{ij}(t)$ may now change with time. This is always the case for the variable age. It also happens when the policyholder changes his domicile or his car, for instance.

Conditionally to Θ , the random variables $N_{i1}, \dots, N_{iT}$ are assumed to be independent and Poisson distributed. Dependence between claim numbers is generated by the residual heterogeneity modeled by Θ . It is therefore relevant to analyze the conditional distribution of Θ . When Θ is gamma distributed, $\Theta \sim \text{Gam}(a, a)$, we have the following:

$$\Theta | N_{i1}, \dots, N_{iT} \sim \text{Gam}(a + N_{i\bullet}, a + \lambda_{i\bullet}) \quad (5)$$

where $N_{i\bullet} = \sum_{t=1}^T N_{it}$ and $\lambda_{i\bullet} = \sum_{t=1}^T \lambda_{it}$.

This immediately implies

$$\mathbb{E}[\Theta | N_{i1}, \dots, N_{iT}] = \frac{a + N_{i\bullet}}{a + \lambda_{i\bullet}} \quad (6)$$

Furthermore, we have that

$$\begin{aligned} \mathbb{E}[N_{i(T+1)} | N_{i1}, \dots, N_{iT}] &= \lambda_{i(T+1)} \\ &\times \mathbb{E}[\Theta | N_{i1}, \dots, N_{iT}] \end{aligned} \quad (7)$$

from which we conclude

$$\mathbb{E}[N_{i(T+1)} | N_{i1}, \dots, N_{iT}] = \lambda_{i(T+1)} \frac{a + N_{i\bullet}}{a + \lambda_{i\bullet}} \quad (8)$$

For instance, for a policyholder having constant expected frequency $\lambda = 0.10$ and a random effect modeled by a gamma distribution with $a = 1.25$, we can draw a table as shown in Table 1.

Table 1 *A posteriori* corrections for a policyholder with expected frequency $\lambda = 0.10$ and $a = 1.25$

$t/N_{i\bullet}$	0(%)	1(%)	2(%)
1	93	167	241
2	86	155	224
3	81	145	210
4	76	136	197
5	71	129	186
6	68	122	176
7	64	115	167
8	61	110	159

This bonus–malus table is not easy to implement in practice. This is why insurance companies resort to so-called bonus–malus scales.

Bonus–Malus Scales

Let us assume a bonus–malus scale with $s + 1$ levels ℓ numbered from 0 to s . To each level ℓ corresponds a premium level r_ℓ , also called *relativity*. The relativities are multiplied by a base premium (BP) to obtain the premium paid by the policyholder (see Table 2).

When the driver makes a claim, he suffers an increase of his position in the scale, resulting in an increase of his premium: this is the malus. When the driver is claim free, he gets a bonus by going down in the scale, resulting in a lower premium. Each bonus–malus system has well-defined transition rules showing the behavior of the policyholders within the scale. The driver never goes below level $\ell = 0$ or above level $\ell = s$.

There is no model to define the transition rules. These rules are set by the insurance company as a function of its commercial approach of the market. The relativities should then be computed in a fair way.

Because the cost of the claims is essentially a function of the third party, it cannot be explained by the behavior of the policyholder. Therefore, the severity of the claims usually is not taken into account in the transition rules. This, however, leads to the hunger for bonus described in the section titled “Bonus Hunger, Moral Hazard, and Signal Theory”.

As an example, let us mention the transition rules of the old Belgian bonus–malus scale (see Table 3). Before 2004, a unique bonus–malus scale was imposed to all insurers by law. Since 2004, the market has been freed. However, most insurers have

Table 2 Description of a bonus–malus scale

Level	Premium	Relativity
s	b_s	r_s
$\vdots$	$\vdots$	$\vdots$
ℓ	$b_\ell = r_\ell \times BP$	r_ℓ
$\vdots$	$\vdots$	$\vdots$
1	b_1	r_1

Table 3 Old Belgian bonus–malus scale

Class	Relativities (%)	Class	Relativities (%)	Class	Relativities (%)
22	200	15	105	7	69
21	160	14	100	6	66
20	140	13	95	5	63
19	130	12	90	4	60
18	123	11	85	3	57
17	117	10	81	2	54
16	111	9	77	1	54
		8	73	0	54

applied only cosmetic changes to the old scale we present now. The scale has 23 steps numbered 0 to 22. A new driver enters the scale at level 11 (or 14 if he has professional use of the car). Each year the policyholder goes one step down. Each reported accident is penalized by a five steps increase. In other words, when the policyholder does not claim, he gets a one step bonus; if he reports one accident, he has a malus of four steps; if he reports two claims, he has a malus of nine steps, etc. The policyholder never goes below step 0 or above step 22. Moreover, there is a superbond rule allowing a driver being above level 14, with four consecutive claim-free years to be sent to level 14.

In practice, such a bonus–malus scale can be represented by a finite Markov chain. Indeed, the knowledge of the current level and of the number of claims of the current year suffices to determine the next level in the scale. Moreover, the Markov chains are generally irreducible, meaning that all states are always accessible in a finite number of steps from all other states (having a bonus–malus scale whose associated Markov chain is not irreducible would be difficult to justify to the policyholders). Moreover, bonus–malus scales have a bonus level with maximal reward: policyholders being in that level will remain in that level after a claim-free year. Both these properties ensure that the Markov chain associated to the bonus–malus scale has a limiting distribution, or steady state distribution, which is also the stationary distribution.

Norberg [4] suggested the minimization of the expected squared difference between the true relative premium Θ (i.e., the correction to apply to the policyholder according to our model with a random effect), and the relative premium r_L of the scale (i.e., the correction to apply according to the simplified model based on a bonus–malus scale), $\mathbb{E}(\Theta - r_L)^2$,

to get the relativities r_ℓ . Pitrebois *et al.* [5] have extended this methodology to the case with *a priori* segmentation. It gives the following:

$$r_\ell = \frac{\sum_{k=1}^m w_k \int_0^\infty \theta \pi_\ell(\lambda_k \theta) dF_\Theta(\theta)}{\sum_{k=1}^m w_k \int_0^\infty \pi_\ell(\lambda_k \theta) dF_\Theta(\theta)} \quad (9)$$

where

- F_Θ is the cumulative density function (cdf) of Θ ;
- w_k is the weight of the k th class;
- λ_k is the expected frequency within the k th class;
- $\pi_\ell(\lambda_k \theta)$ is the probability that a policyholder with frequency $\lambda_k \theta$ is at the level ℓ at steady state.

This formula recognizes the interaction between *a priori* and *a posteriori* tarification. Indeed, an insurer using few, or even no *a priori* covariates needs stronger *a posteriori* corrections, whereas an insurer that would be able to discover all the relevant characteristics (even those being hidden) of the driver actually does not need any *a posteriori* correction. Note that the old bonus–malus systems in force in the EU did not recognize that fact. Insurers were, indeed, allowed to apply the *a priori* segmentation of their choice, whereas the bonus–malus scale was imposed by law, independently of the *a priori* segmentation.

Results regarding the Belgian bonus–malus scale have been obtained by Pitrebois *et al.* [6], based on real life data.

Bonus Hunger, Moral Hazard, and Signal Theory

An important effect of bonus–malus scales is the so-called bonus hunger. Policyholders causing small claims may be tempted to defray themselves the third party to avoid maluses. This strategy is very natural and implies censoring: small claims are not observed. Actually, the bonus hunger helps the insurer in reducing its administrative expenses. Indeed, the latter are the most important (in relative terms) for small claims. Not being reported to the insurer, administration costs are saved.

Lemaire [7] has described an algorithm allowing the policyholder to obtain his optimal retention as a function of his level in the scale, as well as his claiming frequency.

The bonus hunger effect is important to cope with when an insurance company wants to change a bonus–malus scale. The new scale may indeed have another effect on the bonus hunger of the policyholders. Lemaire’s algorithm allows to find the optimal strategy of the policyholders. However, it requires the true claim amount distribution and the true frequency distribution. These are not easy to obtain owing to the censoring effect. Attempts to cope with these parameters have been done in [8] and in [3].

Another reason why *a posteriori* rating schemes are more relevant is that they counteract moral hazard. When the premium is fixed, together with the absence of deductible (which is often the case in motor third party liability insurance), there is no incentive for the policyholder to avoid claims. Because (s)he knows that (s)he has a cover, the policyholder may adopt a more aggressive style of driving without having to support the potential financial consequences. This would be the realization of moral hazard risk: the cover is now influenced consciously by human behavior. It is clear that moral hazard should be avoided as far as possible. Imposing deductibles is a classical way to counteract moral hazard. *A posteriori* rating schemes clearly allow for counteracting moral hazard behaviors: if the policyholder claims, his (her) premium will increase at the next renewal. So there is a financial incentive for the policyholder not to claim.

Bonus–malus scales may also be used to discover the hidden characteristics of the policyholders.

Assume that an insurer proposes two scales to its policyholders: a soft scale (with mild penalties) and a strong scale (with heavy maluses). Bad risks (not necessarily revealed through their *a priori* characteristics) will be tempted to choose the soft scale. By doing so, they actually signal themselves to the insurance company. This is an application of the signal theory.

Burn-in Testing: Its Quantification and Applications

Definitions

1. In MIL-STD-883C [1, 2], method 1015.3, burn-in test is defined as follows:
Burn-in is a test performed for the purpose of screening or eliminating marginal devices, those with inherent defects or defects resulting from manufacturing aberrations which cause time and stress dependent failures (*see Reliability Integrated Engineering Using Physics of Failure; Hazard and Hazard Ratio*).
2. Kuo and Kuo in [3] define the burn-in more clearly as follows:
Burn-in combines the appropriate electrical conditions with the appropriate thermal conditions to accelerate the aging of a component or device. In other words, burn-in is a process during which electronic components or systems are operated under specific electrical and thermal conditions to determine the early life of components and products (*see Product Risk Management: Testing and Warranties; Design of Reliability Tests; Repair, Inspection, and Replacement Models*) and the substandard ones are forced to fail and thus removed from the production.

Why Burn-in?

In reliability and risk analysis (*see Multistate Systems; Imprecise Reliability; Lifetime Models and Risk Assessment; Mathematics of Risk and Reliability; A Select History*) the lifetime of a population of products are often described by using a graphical model called the *bathtub curve* (*see Hazard and Hazard Ratio; Accelerated Life Testing*) in Figure 1 [4]. The bathtub curve is composed of three periods: an infant mortality period with a decreasing failure rate, followed by a life period known as *useful life* with a low, relatively constant failure rate, and concluding with a wear-out period that exhibits an increasing failure rate.

Many types of equipment and systems exhibit an inherent decreasing failure rate characteristic during their early operating life. A relatively high early failure rate is usually attributed to the inherent variability in the production process. Burn-in has long been recognized as a useful method for detecting and eliminating components and systems with early failure risk before customer delivery. Without burn-in, defective components are delivered to customers, resulting in costly field repairs, damage to the reputation of the manufacturers, and thus loss of business.

Also from Figure 1, if the operating temperature K is higher, then the product's life will be shortened, as well as the burn-in period. This is the reason why many products will be burned-in at a higher temperature before they are released to customers, thus saving time and cost of the testing process.

Burn-in testing is not a product improvement technique. Submitting a population of a product to burn-in does not improve each unit's individual reliability. However, burn-in improves the reliability of the whole population by weeding out the bad portion of the population, resulting in a more reliable and homogeneous population of units. Also, burn-in usually provides insightful information about the various failure mechanisms that cause early failures and provides valuable feedback to the quality and reliability engineers who oversee the design and the manufacturing process to help them analyze the variations and causes that lead to the emergence of these early failure mechanisms.

Burn-in Test Types and Applications

The methods used to stress all the nodes in a device depend on the complexity and failure mechanisms of the integrated circuit (IC). Therefore, they fall into the following categories:

1. Static burn-in test

The simplest type of burn-in test is static, or steady-state, burn-in method. Static burn-in maintains a steady-state bias on each device under high temperature for a number of hours to accelerate the migration of impurities to the surface so that a failure will occur. A static system is cheaper and simpler, and is used to precipitate contamination-related failure mechanisms. It is, however, less effective than dynamic burn-in for large scale integration (LSI) and very large scale integration (VLSI) devices.

Figure 1 The bathtub curve

2. Dynamic burn-in test

The dynamic burn-in test method uses power sources such as voltage, clock signals, and address signals to ensure all internal nodes are reached during temperature stressing. It is more effective at detecting early failures in complex devices. It is also more expensive and requires more dedicated burn-in boards. It should be noted that a dynamic burn-in system can also be used for static burn-in, but not the other way around.

3. Test during burn-in

A subset of dynamic burn-in is test during burn-in (TDBI). TDBI adds functional testing and, possibly, monitoring of component outputs to show how they are responding to specific input stimuli. TDBI is the most comprehensive burn-in technique, especially when coupled with scan-based technology. It has been used primarily for dynamic random access memories (DRAMs), but it is applicable to all large memories owing to their long electrical test times. Normally, the electrical testing is performed after burn-in to detect any potential failures that may occur during their useful life period. TDBI is not appropriate for the microprocessors and other VLSI circuits of EPROM (erasable and programmable read only memory).

4. High-voltage stress tests

High-voltage stress tests are categorized as burn-in screens because of their device-aging acceleration features due to the application of higher voltage, time,

and temperature. For these tests, the distribution of the voltage stress throughout the IC is accomplished by carefully designed dynamic and functional operation. IC memory suppliers have used high-voltage stress tests in lieu of dynamic burn-in as a means to uncover oxide defects in metal oxide semiconductor (MOS) ICs. A typical high-voltage stress test involves cycling through all addresses (for a memory) using selected memory data patterns for 2 s, both high and low (logically speaking), with 7.5 V forcing function being applied, for a 5-V rated part, for example.

Other classifications have been proposed by Foster [5], according to which the generally used burn-in methods can be categorized as follows:

1. Elevated temperature plus power – the cheapest but the least effective method.
2. Elevated temperature plus power with all inputs reverse biased, or the so-called high-temperature reverse bias (HTRB) method – a method with moderate cost and reasonable effectiveness for most devices.
3. Elevated temperature, power, dynamic excitation of inputs, and full loading of all outputs – an effective and expensive method.
4. Optimum biasing combined with temperature in the range of 200–300 °C, or the so-called high-temperature operating test (HTOT) – an expensive and difficult-to-carry-out method, which is

not applicable to plastic devices owing to the high temperatures involved.

Burn-in Test Conditions

In MIL-STD-883C, the following six basic test conditions are specified for the burn-in test:

Test condition A – steady state, reverse bias

This test condition is suitable for use on all types of circuits, both linear and digital. In this test, as many junctions as possible will be reverse biased to the specified voltage.

Test condition B – steady state, forward bias

This test condition can be used on all digital type circuits and some linear types. In this test, as many junctions as possible will be forward biased to the specified voltage.

Test condition C – steady state, power, and reverse bias

This test condition can be used on all digital type circuits and some linear types where the inputs can be reverse biased and the output can be biased for maximum power dissipation or *vice versa*.

Test condition D – parallel or series excitation

This test condition is suitable for use on all circuit types. Parallel or series excitation, or any combination thereof, is permissible. However, all circuits must be driven with an appropriate signal to simulate, as closely as possible, circuit application, and all circuits should have the maximum load applied. The excitation frequency should not be less than 60 Hz.

Test condition E – ring oscillator

In this test condition, the output of the last circuit is normally connected to the input of the first circuit. The series will be free running at a frequency established by the propagation delay of each circuit and the associated wiring, and the frequency shall not be less than 60 Hz. In the case of circuits that cause phase inversion, an odd number of circuits shall be used. Each circuit in the ring shall be loaded to its rated maximum capacity.

Test condition F – temperature-accelerated test

Under this test condition, microcircuits are subjected to bias(es) at an ambient test temperature, typically from 151 to 300 °C, which considerably exceeds their maximum rated junction temperature. It is generally

found that microcircuits will not operate properly at these elevated temperatures. Therefore, special attention should be given to the choice of bias circuits and conditions to assure that important circuit areas are adequately biased without incurring any damaging overstresses to other areas of the circuit. To select the accelerated test conditions properly, it is recommended that an adequate sample of devices be exposed to the intended high temperature while measuring voltage(s) and current(s) at each device terminal to assure that the applied electrical stresses do not induce damaging overstresses.

The specified test temperature is the minimum actual ambient temperature to which all devices in the working area of the chamber shall be exposed. This should be assured by making whatever adjustments are necessary in the chamber profile, loading, location of control or monitoring instruments, and the flow of air or other suitable gas or liquid chamber medium. The ambient burn-in test temperature for conditions A–E shall be 125 °C minimum.

Burn-in Time Determination

The determination of the correct burn-in time requires the use of reliability methodologies, as well as the costs involved, *versus* achievement of the optimum failure rate [6].

Method 1: Determine the Burn-in Time Using a Histogram

A histogram is a very quick and useful method to determine the burn-in time when a large amount of time-to-failure data are available from testing or field returned products. The following example illustrates this method in details.

Example 1 The time-to-failure data are as given in columns 1 and 2 in Table 1 [1]. The data are based on 900 devices subjected to burn-in, and their performance is monitored in 10-h intervals to determine the number of devices that fail in each interval. Draw the failure rate histogram and decide the best burn-in time.

Solution to Example 1

1. Calculate the number of units surviving after each 10-h period and list them in column 3 of Table 1.

Table 1 Data of failures

1	2	3	4
Life (h)	Number of failures, N_F	Number of units surviving period, N_{BP}	Failure rate $\hat{\lambda} = \frac{N_F(\Delta T)}{N_{BP}(T) \times \Delta T}$
0–10	33	$900 - 33 = 867$	$\frac{33}{900 \times 10} = 0.003667$
10–20	31	$867 - 31 = 836$	$\frac{33}{900 \times 10} = 0.003667$
20–30	28	$836 - 28 = 808$	$\frac{33}{900 \times 10} = 0.003667$
30–40	25	$808 - 25 = 783$	$\frac{33}{900 \times 10} = 0.003667$
40–50	23	$783 - 23 = 760$	$\frac{33}{900 \times 10} = 0.003667$
50–60	21	$760 - 21 = 739$	$\frac{33}{900 \times 10} = 0.003667$
60–70	20	$739 - 20 = 719$	$\frac{33}{900 \times 10} = 0.003667$
70–80	19	$719 - 19 = 700$	$\frac{33}{900 \times 10} = 0.003667$
80–90	18	$700 - 18 = 682$	$\frac{33}{900 \times 10} = 0.003667$
90–100	18	$682 - 18 = 664$	$\frac{33}{900 \times 10} = 0.003667$
100+	664	$664 - 664 = 0$	–
$N = 900$			

- Use the following equation to estimate the failure rates in each 10-h period and list them in column 4.

$$\hat{\lambda}(T) = \frac{N_F(\Delta T)}{N_{BP}(T) \times \Delta T} \quad (1)$$

where $\hat{\lambda}(T)$: average estimate of the failure rate in each ΔT time interval, $N_F(\Delta T)$: number of devices failing in ΔT time interval, $N_{BP}(T)$: number of devices at the beginning of each ΔT interval, and ΔT : time interval for which the $\hat{\lambda}(T)$ is calculated.

- Draw the histogram in Figure 2.
- In Figure 2, the failure rate decreases with time and approaches a stable, or constant, value at about 84 h. So the optimum burn-in time is about 84 h.

Figure 2 The histogram of the failure rate function

Method 2: Determine the Burn-in Time Using the Mixed Population Model

In contrast to the histogram method, the mixed population model provides an analytical way to decide the best burn-in time, as well as to quantify the percentages of different subpopulations in the whole product.

Let p denote the proportion, or percentage, of the i th subpopulation in the entire population, where

$$\sum_{i=1}^n p_i = 1, \quad 0 \leq p_i \leq 1 \quad (2)$$

The reliability and the probability density functions are then given, respectively, by

$$R(T) = \sum_{i=1}^n p_i R_i(T) \quad (3)$$

and

$$f(T) = \sum_{i=1}^n p_i f_i(T) \quad (4)$$

where $R(T)$ and $f(T)$ are the reliability function and the *pdf* of the entire population, respectively.

The failure rate function of the population (*see Reliability Data*) is given by

$$\lambda(T) = \frac{f(T)}{R(T)} = \frac{\sum_{i=1}^n p_i f_i(T)}{\sum_{i=1}^n p_i R_i(T)} \quad (5)$$

This model can be used to describe the failure behavior of the population, which contains n mutually exclusive and well-separated subpopulations with early, chance, and wear-out failure modes. This characteristic makes it very flexible to give a wide variety of failure rate curves, including the classic bathtub curve. Usually, there are three subpopulations, which are taken to be Weibull distributed.

Once the failure rate function, $\lambda(T)$, is determined, it is easy to plot this function *versus* time and find out the best burn-in time, at which the failure rate approaches a low and constant value.

Example 2 A total of 1000 units are tested to failure and after analysis we have the following results:

100 of them are early failures with the following Weibull distribution parameters: $\gamma = 0$, $\beta = 0.5$, $\eta = 20$ h; 700 of them are chance failures having a constant failure rate of $\lambda = 0.0003$ fr/h; and 200 of them are wear-out failures with the following Weibull distribution parameters:

$$\gamma = 0, \beta = 3.5, \eta = 4000 \text{ h}$$

Write down the equation for $\lambda_{e,c,w}(T)$, plot it, and decide the best burn-in time.

Solution to Example 2

The percentage of early failures in the entire population is

$$p_1 = \frac{N_1}{N} = \frac{100}{1000} \times 100\% = 10\% \quad (6)$$

the reliability function is

$$R_1(T) = e^{-\left(\frac{T}{\eta}\right)^\beta} = e^{-\left(\frac{T}{20}\right)^{0.5}} \quad (7)$$

and the *pdf* is

$$\begin{aligned} f_1(T) &= \frac{\beta}{\eta} \left(\frac{T}{\eta}\right)^{\beta-1} e^{-\left(\frac{T}{\eta}\right)^\beta} \\ &= \frac{0.5}{20} \left(\frac{T}{20}\right)^{-0.5} e^{-\left(\frac{T}{20}\right)^{0.5}} \end{aligned} \quad (8)$$

The percentage of chance failures in the entire population is

$$p_2 = \frac{N_2}{N} = \frac{700}{1000} \times 100\% = 70\% \quad (9)$$

the reliability function is

$$R_2(T) = e^{-\lambda T} = e^{-0.0003T} \quad (10)$$

and the *pdf* is

$$f_2(T) = \lambda e^{-\lambda T} = 0.0003 e^{-0.0003T} \quad (11)$$

The percentage of wear-out failures in the entire population is

$$p_3 = \frac{N_3}{N} = \frac{200}{1000} \times 100\% = 20\% \quad (12)$$

Figure 3 Failure rate curve for equation (5)

the reliability function is

$$R_1(T) = e^{-\left(\frac{T}{4000}\right)^{3.5}} \quad (13)$$

and the *pdf* is

$$\begin{aligned} f_1(T) &= \frac{\beta}{\eta} \left(\frac{T}{\eta}\right)^{\beta-1} e^{-\left(\frac{T}{\eta}\right)^{\beta}} \\ &= \frac{3.5}{4000} \left(\frac{T}{4000}\right)^{2.5} e^{-\left(\frac{T}{4000}\right)^{3.5}} \end{aligned} \quad (14)$$

Using equation (5)

$$\begin{aligned} \lambda_{e,c,w}(T) &= \frac{f(T)}{R(T)} = \frac{\sum_{i=1}^n p_i f_i(T)}{\sum_{i=1}^n p_i R_i(T)} \\ &= \frac{10\% \cdot \frac{0.5}{20} \left(\frac{T}{20}\right)^{-0.5} e^{-\left(\frac{T}{20}\right)^{0.5}} + 70\% \cdot 0.0003 e^{-0.0003T} + 20\% \cdot \frac{3.5}{4000} \left(\frac{T}{4000}\right)^{2.5} e^{-\left(\frac{T}{4000}\right)^{3.5}}}{10\% \cdot e^{-\left(\frac{T}{20}\right)^{0.5}} + 70\% \cdot e^{-0.0003T} + 20\% \cdot e^{-\left(\frac{T}{4000}\right)^{3.5}}} \end{aligned} \quad (15)$$

It may be seen from Figure 3 that the failure rate curve has an initial period during which the failure rate decreases sharply to a constant, useful life level, stays at this level for quite a long period,

and then increases as wear-out sets in. The burn-in time is the time after which the failure rate remains constant. For this numerical example the burn-in time is approximately $T = 600$ h.

DIMITRI B. KECECIOGLU AND XIAOFANG
CHEN

1,3-Butadiene

Physical and Chemical Characteristics

1,3-Butadiene (BD) (CAS #106-99-00) is a colorless gas with a structure consisting of four carbons linked by two double bonds at the first and third carbons (MW = 54.1). BD is flammable with a lower explosion limit of 2% (20 000 ppm). It is a major monomer used in the manufacture of rubber and plastics. During World War II, BD was used in large quantities to make synthetic rubber to replace the supplies of natural rubber that were no longer available to the allied forces. At that time, BD was considered to have low toxicity and the occupational threshold limit value was set at 1000 ppm (the level of exposure that the typical worker can experience without an unreasonable risk of disease or injury).

Exposure Potential

Exposure to BD outside the occupational arena is common [1], but this occurs at lower concentrations. Average annual ambient air concentrations in the United States are reported to range from 9 ppt to 3.2 ppb with an overall national mean concentration of 0.12 ppb. Motor vehicle emissions are the largest source of ambient BD, but BD is also present in cigarette smoke and in emissions from other combustion sources.

Acute Toxicity

Extremely high concentrations of BD (>100 000 ppm) cause irritation of the respiratory tract, eyes, and skin and induce suppression of the central nervous system in both animals and humans [2].

Noncancer Chronic Toxicity

Noncancer effects of BD exposure have been studied in animals. The reproductive and developmental toxicity of BD was studied in rats and mice [3] exposed to up to 1000 ppm BD on critical gestation days. No fetal toxicities were observed in rats but mice exposed to as low as 200 ppm BD had fetal anomalies. In bioassay studies, in which animals are

exposed to varying levels of BD over approximately 2 years, atrophy of the gonads was observed in male mice at exposure levels of 625 ppm BD or higher, and in female mice after exposure to 62.5 ppm [4, 5]. No such effects were observed in rats [6]. Rats and mice also exhibited different responses to BD on the hematopoietic and immune systems. Rats exposed for 13 weeks to 8000 ppm BD showed no signs of general toxicity, including hematotoxicity [7]. Mice exposed in a similar fashion had suppressed immune systems and toxicity to the bone marrow [8]. Later studies confirmed the hematotoxicity of BD in mice, which developed a macrocytic anemia following chronic, near lifespan exposure to 1250 ppm BD, indicating that the bone marrow was a target organ for BD toxicity in mice [9].

Potential for Carcinogenicity

Because BD was used in such large volumes, 2-year rodent bioassays were conducted to determine if rats or mice would suffer any adverse health effects, and in particular, cancer, if they were exposed to BD at selected air concentrations for most of their lifetimes. In the rat bioassay, animals were exposed to 1000 or 8000 ppm for about 2 years [6]. In line with previous expectations, the BD showed little noncancer toxicity and was a weak carcinogen in the rats. The tumors observed were mainly in hormonally dependent tissues (mammary glands and uterus in females; thyroid, pancreas, and testis in males) and only at the higher exposure concentration, with the exception that an increase in mammary gland tumors was observed in females at both exposure concentrations. In contrast to the rats, the mice exposed over most of their lifespan to much lower concentrations of BD (6.5–1250 ppm) indicated that BD was a potent multisite carcinogen in this species, resulting in neoplasms of the heart, lung, mammary glands, and ovaries [4, 5]. Increased lung tumors were observed in female mice even at the lowest exposure concentration of 6.25 ppm BD. The incidence of thymic lymphomas in the mice exposed to concentrations of 200 ppm BD or higher led to high mortality, but this result was considered to be the result of activation of an endogenous retrovirus in the specific strain of mice tested and not relevant to risk in humans [9].

Metabolism of BD

A major question raised by the animal studies was which species, if either, was predictive of human sensitivity to BD. In an attempt to help answer this question, many researchers studied differences in how the rats and mice metabolize BD [2]. Rats, mice, and humans all have common ways to get rid of foreign organic compounds through metabolism (alteration of the form of the chemical). Enzymes in the body first oxidize the compound to a reactive state, which can then be hydrolyzed to a form that can be excreted in the urine. For 1,3-butadiene, enzymatic oxidation can lead to formation of reactive epoxides at either or both of the double bond sites. These epoxides can then be hydrolyzed to diols, which form conjugates with reduced glutathione, and are then excreted in the urine as mercapturic acids. Unfortunately, sometimes the reactive form (the epoxides) reacts with the genetic material, the DNA, before the epoxide can be hydrolyzed for excretion. This reaction with DNA can lead to alterations (mutations) in the genetic material that result in loss of control of cell growth, and cancer. Thus the oxidation of BD is considered to be a toxication pathway, while hydrolysis and conjugation are detoxication pathways.

BD can be oxidized enzymatically to one of the three reactive epoxides, a monoepoxide, a diepoxide, or an epoxydiol. The epoxydiol is a compound in which one double bond is oxidized to an epoxide and the second double bond is occupied by two hydroxyl groups. This epoxide can be formed by hydrolysis of either the monoepoxide or the diepoxide. The diepoxide is a much more potent mutagen than monoepoxide or the epoxydiol [10] and the basic difference between the rats and mice was found to be that the mice form much more of the diepoxide than do the rats. This evidence is based on a comparison of metabolites in the blood of exposed rats and mice and suggestive evidence based on the urinary metabolites of BD in humans, rats, and mice [11].

Another difference between the species that influences the toxicity of BD is the balance between the activities of the oxidizing enzymes (forming toxic, reactive metabolites) and the hydrolyzing or conjugating enzymes (detoxification activities) in the livers of the different species. The oxidizing enzymes and the hydrolytic enzymes are both located in the microsomes located in the rough endoplasmic reticulum surrounding the nucleus where the DNA

is located [12]. If the hydrolyzing enzymes are active enough, the toxic oxidation products can be detoxicated quickly before they can react with the DNA. If the hydrolyzing activity is low, the monoepoxide can be further oxidized to the much more potent mutagen, the diepoxide. Among several species studied, the mouse has the lowest liver hydrolytic activity and also the highest ratio of oxidation to hydrolysis activity. Primates, including humans, have about a 30-fold higher liver hydrolytic activity than the mouse and a ratio of oxidation activity over hydrolytic activity about 1/10th that of the mouse. The rat has a similar ratio of these activities as that of the primates [12]. This imbalance between the toxication and the initial detoxication pathways in the mouse suggests one reason for the exquisite sensitivity of the mouse to the carcinogenic action of BD.

Metabolites as Biomarkers for BD

Biomarkers are endogenous indicators of the exposure to or the effect of exposures to foreign substances and can be useful in risk assessment. Biomarkers of exposure can help define exposures of individuals in epidemiology studies. A major study conducted in Czechoslovakian workers at a butadiene production plant compared exposures of individual worker based on in-depth occupational hygiene documentation, including personal monitors, with exposures determined by the blood or urine concentrations of selected metabolite biomarkers in the workers [13]. The biomarker that agreed best with the occupational hygiene measurements was a hemoglobin adduct formed from the epoxy diol metabolite [14].

The mercapturic acids excreted in the urine were also found to be useful as biomarkers of exposure. The urinary mercapturic acids allow one to distinguish between the mercapturic acid formed from conjugation of glutathione directly with the monoepoxide and the mercapturic acid formed by conjugation with the hydrolyzed monoepoxide (the epoxy diol). These two types of mercapturic acids can be used to provide a rough estimate of the hydrolytic detoxication activity occurring in different species. The ratios of the amount of these mercapturic acids in the urine indicate that mice have the least hydrolytic detoxication, rats are intermediate, and humans have the highest hydrolytic activity [12].

The urinary biomarkers of the formation of the different types of butadiene epoxides are of special interest. Some urinary biomarkers are compounds that are the breakdown products of the interaction of hemoglobin or DNA with the epoxides. Because the diepoxide appears to be the major genotoxic and carcinogenic metabolite of BD, a large research effort has been focused on developing a biomarker for the formation of the diepoxide. Recently a diepoxide-specific adduct (to DNA or to hemoglobin) has been identified and should be useful in determining the amount of the potent mutagen formed after exposure to BD [15]. A comparison of the biomarkers in the urine of rats, mice, and humans confirmed that much more of the diepoxide is formed in mice than in rats, and that human metabolism of BD is more similar to that of rats than that of mice [11, 12, 15]. A confirmation of the low amount of the diepoxide formed in humans is a biomarker of an effect of the BD metabolite. Exposure of human lymphocytes to the diepoxide *in vitro* results in induction of sister chromatid exchanges (SCE) in the cells, but no such effects were observed in workers exposed to 1–3 ppm BD [14]. An indication of a possible sensitive subpopulation has been found in similar *in vitro* studies. Lymphocytes from persons that do not have one of the conjugating detoxication enzymes are more sensitive to induction of SCEs following BD exposure than are lymphocytes from persons with the conjugating enzyme [14].

Toxicity Based on Epidemiology Studies

With the species dependency of the BD toxicity found in the animal studies, risk assessors turned to epidemiology studies, which determine associations between BD exposures and adverse health effects in humans. The epidemiology studies focused mainly on two groups of workers: the styrene–butadiene synthetic rubber (SBR) workers and the workers at BD production facilities. By far, the largest group was the workers in the SBR industry (approximately 18 000), and there was evidence of an association between BD exposure and an increase in mortality from leukemia (all types combined) [16, 17]. In later follow-up studies, it was confirmed that working in the SBR industry is associated with an increased risk of leukemia [18], but it has not been possible to tease out the responsible agent as being either butadiene or styrene. However, styrene has not been

associated with leukemia in workers exposed to high concentrations of styrene in other industries [16].

In the smaller group of workers producing BD (approximately 2800 workers), a group in which there was less confounding due to exposure to chemicals other than BD, deaths from lymphohematopoietic cancers (non-Hodgkin's lymphoma and to a lesser extent, leukemia) were increased [19] but no exposure–response relationship was found. In summary, current epidemiology provides reasonable evidence that work in the SBR industry is associated with increased risk of lymphohematopoietic cancer, but the causative agent(s) is not completely certain.

Regulatory Values

Various agencies have performed risk characterizations on the health effects of exposure to BD. The noncancer health risks are usually based on animal studies, while the cancer risks are based on epidemiology studies. The International Agency for Research on Cancer classifies BD as a known human carcinogen (Group 1) based on sufficient animal and human data. The US Environmental Protection Agency (EPA) classifies BD as carcinogenic to humans by inhalation with a lifetime risk of 3×10^{-5} for a $1 \mu\text{g m}^{-3}$ (0.45 ppb) exposure, based on the epidemiology studies of the SBR cohort. The same value calculated by the California EPA [20] is specified as a cancer potency factor of 1.7×10^{-4} . The United Kingdom, using an expert panel approach, concluded that there was no evidence of increased health risk in workers exposed to less than 1000 ppb and recommended 1 ppb as a protective level for the annual average for an ambient lifetime exposure [21]. The United States Occupational Safety and Health Administration has lowered its permissible exposure limit for workers from 1000 to 1 ppm (8-h time weighted average) and its short-term limit (15 min) to 5 ppm [22]. The American Conference of Industrial Hygienists lists a threshold limit value for BD as 2 ppm, which is the airborne exposure concentration for which it is believed that nearly all workers can be exposed on a daily, 8-h time weighted average basis, without adverse health effects [23].

Cancer Risk Evaluation from Animal Studies

ROGENE F. HENDERSON

Cancer Risk Evaluation from Animal Studies

Just as animal models are used in preclinical trials of pharmaceutical agents before testing is begun in humans, studies of chemicals found in the workplace or in the general environment are conducted in experimental animals to assess potential human health risks. In addition to identifying adverse responses prior to human trials, animal studies are performed in drug development programs to estimate and compare therapeutic doses with those doses that induce adverse reactions. The ratio between the toxic dose and the therapeutic dose, called the *therapeutic index*, is a measure of the relative safety of a drug for a specific treatment (*see Toxicity (Adverse Events)*). Adverse health concerns are minimized for drugs that produce therapeutic effects at doses much lower than those that cause toxic effects. Drugs with a low therapeutic index require much more monitoring to achieve the therapeutic effect with minimal toxicity. In contrast to pharmaceuticals, a therapeutic value is not a recognized benefit from environmental or occupational exposure to toxic chemicals and carcinogens (*see Environmental Carcinogenesis Risk*). Exposure standards for such agents are typically based on the nature of the induced health effect and its potency. The likelihood of an adverse effect occurring in humans is often reduced when actual environmental or occupational exposures are substantially lower than those that induce toxic effects in animal models.

The utility of experimental animal studies for predicting human disease is based on similarities between species in biological processes such as absorption and metabolism of xenobiotic agents and in disease induction mechanisms. Because it is unethical to test for adverse health effects, such as cancer, in humans through intentional exposures, animal models are widely used to screen and evaluate agents for potential human health risks. Also, animal studies have other advantages compared to human studies. For example, animal studies eliminate the need to wait for a high incidence of human cancers, which may take as long as 30 years beginning from time of first exposure to clinical manifestation of disease [1], before implementing public health protective strategies. In addition, because exposure

conditions can be finely controlled in animal studies, they are easier to interpret, assign causality, and estimate response potency. In contrast, epidemiological studies of occupational or environmental human cancer risks typically have limited sensitivity and limited exposure information, especially at times early in tumor development, and when confounding factors are not always known or accounted for [2]. The major disadvantages of animal studies are that they require extrapolations across species and dose. In addition, animal studies do not capture the full range of interindividual variability in disease susceptibility due to differences in genetic factors, health status, diet, life style, and exposures to other agents.

Most national and international public health agencies, including the International Agency for Research on Cancer (IARC) [1], the National Toxicology Program (NTP) [3], and the United States Environmental Protection Agency (US EPA), [4], utilize data from animal studies to make decisions on cancer risk in humans. The perspective adopted by these agencies that in the absence of adequate data in humans, “it is biologically plausible that agents for which there is sufficient evidence of carcinogenicity in experimental animals also present a carcinogenic hazard to humans” is based on the fact that all known human carcinogens that have been studied adequately in experimental animals produce positive carcinogenic results [1]. Hence, even in the absence of any human data, public health agencies classify agents as possibly/probably or likely to be carcinogenic in humans [1] or reasonably anticipated to be a human carcinogen [3] if there is sufficient evidence in animals demonstrating (a) increased incidence of malignant or combined malignant and benign tumors in two or more species or at multiple sites; or (b) increased incidence in two or more independent studies in one species; or (c) increased incidence in a single study in one species if malignant tumors occur to an unusual degree in incidence, site, type, or age of onset. Several agents that were considered to be possible human carcinogens based on animal data were later confirmed as human carcinogens when reliable epidemiology data (usually occupational exposures) became available; among others, these include 1,3-butadiene, cadmium, diethylstilbestrol, formaldehyde, ethylene oxide, and vinyl chloride [5].

This chapter focuses on the following: (a) design of carcinogenicity studies on environmental agents

in laboratory animals, (b) evaluation of experimental carcinogenicity studies, and (c) assessment of human cancer risk based on animal tumor data.

Design of Carcinogenicity Studies on Environmental Agents in Laboratory Animals

The design of experimental carcinogenicity studies is critical for the identification of adverse health effects caused by specific environmental agents (*see Environmental Hazard*) and the characterization of dose–response relationships (*see Dose–Response Analysis*). For example, due to design deficiencies, including small group size, lack of controls, short study duration, and low levels of exposure, early studies on *benzene* (*see Benzene*) in animals, failed to detect carcinogenic effects, even though epidemiology studies had demonstrated a causal association between benzene exposure and leukemia in humans. Subsequent studies that were better designed established benzene as a potent, multisite carcinogen in rats and mice [6, 7].

The Test Chemical

In order to ensure that the agent under study is responsible for any observed effects and that contaminants are not the cause or modifier of that response, the chemical should be tested at high purity. However, testing of technical grades of certain chemicals may be done to mimic human exposures. Prior to exposing animals to the agent, it is necessary to demonstrate its purity and its stability under the conditions of exposure and storage. If the agent degrades or evaporates during exposure, the accuracy of the targeted administered dose is compromised and degradation products may contribute to any observed response.

Animal Models

Rats and mice are the two species most frequently used in cancer bioassays because (a) they are responsive to tumor induction resulting from exposure to carcinogens, (b) they have life spans of about 2.5 years, and (c) studies of up to 1000 animals can be performed in reasonably sized animal rooms. The selected strains of animal models

should have good longevity, genetic stability, and few spontaneous diseases that might shorten their life span, mask any chemical-induced effects, or impair metabolism/elimination of the test agent [8]. Importantly, it is usually difficult to detect a chemically induced response in an organ with a high natural or background tumor rate. Both sexes of two species are typically used to identify any sex-specific responses and to confirm multiple species effects. Although most carcinogenicity studies are conducted in few strains of rats and mice, suggestions have been made to use multiple strains of inbred mice to increase genetic diversity in these bioassays [9]. However, the ability to detect true effects in multiple strains *versus* single strains is a function of the heterogeneity of response across the strains, the strength of response in the sensitive strains, and the inherent rate of the specific tumor types in the various strains [10].

Exposure Duration

Typical carcinogenicity studies in rats and mice involve exposures beginning at 6 weeks of age and continuing for 2 years; this exposure period corresponds roughly with early adulthood through most of an occupational life span [11]. However, because cancer susceptibility may be greater with exposure to mutagens and endocrine disrupting chemicals during growth and early developmental stages, earlier periods of exposure should be included in animal carcinogenicity studies when fetal or childhood exposure to such agents might occur. The 2-year duration limit was selected to minimize late-developing background tumor responses that might preclude the detection of chemical-induced effects [12] and to reflect an occupational life span. Care must be taken, however, to select strains that have reasonable 2-year survival rates. Studies with exposure durations shorter than 2 years are also problematic because of their reduced sensitivity to detect increases in late-appearing tumors that are related to treatment with the test agent [11].

Dose Selection

A major shortcoming of the rodent cancer bioassay is its limited statistical power to detect small to moderate responses [13]. Power is the probability of detecting an effect (rejecting the null hypothesis)

when an effect exists; it is influenced by the sample size, the background rate, and the magnitude of the true response [14]. For example, in order to achieve statistical significance at $p \leq 0.05$ level (the chance of rejecting the null hypothesis when it is true is 5% or less) in a bioassay consisting of 50 animals in each of the three dose groups, a tumor incidence of 38% (19/50) or greater would be necessary in the high dose group if the incidence in the control group was 20% (10/50). If animal group size were only 25, then an incidence of 40% (10/25) would not be statistically significant if the control incidence was 20% (5/25). A negative finding in an underpowered study provides no assurance of the absence of health risks in exposed populations.

Because of the limited statistical power of the cancer bioassay when group size is only about 50 animals per sex dose, higher doses are typically used to identify potential carcinogenic hazards and multiple dose groups are used to characterize dose–response relationships [15, 16]. If carcinogenicity studies were conducted at actual environmental exposure levels, extremely large group sizes (i.e., several hundred to thousands of animals per group) would be needed in order to avoid false negative results.

In order to estimate the maximally tolerated dose or the minimally toxic dose (MTD) for use in the cancer bioassay, data are generated in preliminary prechronic studies typically of 4–13 weeks duration and evaluated for effects on body weight, survival, clinical changes, and incidence and severity of pathologic lesions. The MTD should not cause increases in mortality other than from chemically induced tumors. Therefore, doses that induce life-threatening toxic lesions in a prechronic study would be excluded from use in a cancer bioassay. The identification and use of an MTD is a critical aspect in the design of experimental carcinogenicity studies of low statistical power. Lower doses (1/2 MTD and 1/4 to 1/10 MTD) are used in case the highest dose selected for the chronic study is found to be too high (excessive mortality) and to provide data for dose–response analyses. Pharmacokinetic information is also used to ensure that no more than one of the selected doses is above a level that approaches saturation of absorption, metabolic activation, or detoxification activities. A much better characterization of the true dose–response relationship can be achieved with several dose groups rather than only two widely spaced dose groups.

Evaluation of Experimental Carcinogenicity Studies

The conduct and evaluation of a cancer bioassay requires a multidisciplinary effort, including expertise from toxicologists, laboratory animal veterinarians, chemists, histologists, pathologists, cellular/molecular biologists, and statisticians. The interpretation of tumor data may be affected by the thoroughness of the histopathological evaluations, methods of statistical analysis, and mechanistic considerations.

Histopathology

The detection of toxic effects and neoplastic lesions in animals depends on the thoroughness of the necropsies and the histopathologic examinations performed. The US NTP requires microscopic examination of all organs and tissues, approximately 40 per animal [17]. In some cases, multiple sectioning of an organ in exposed and control groups may be necessary to obtain a truer estimate of the incidence of neoplastic lesions, especially for small lesions that may not be detected at necropsy [18]. Although diagnostic criteria have been established for most observable lesions, it is not unusual for pathologists to disagree in their judgment of lesions, especially those that are part of a continuum of progressive change. After diagnoses by the study pathologist, all NTP studies undergo an independent quality assessment (QA) pathology review. This is followed by a pathology working group review (typically 8–10 pathologists) that seeks to resolve discrepancies in diagnoses between the original and the QA pathologists [19]. Multiple independent evaluations provide greater confidence on the reliability of the histopathology data.

In addition to statistical analyses described below, several additional factors may contribute to the interpretation of tumor data, including: (a) the occurrence of uncommon *versus* common tumors, (b) evidence of progression of lesions, such as benign to malignant where it is appropriate to combine [20], (c) tumor occurrence with reduced latency, (d) multiplicity in a site-specific tumor response, (e) evidence of metastases, and (f) supporting evidence of proliferative preneoplastic lesions at the same site or detection of the same lesion in the other sex or species. Because cancer development is a multistep process with a long time period between exposure and

manifestation of metastatic neoplasia, evidence of enhanced disease progression (e.g., reduced latency, tumor multiplicity, metastasis) in an animal study is another indication that the agent promotes cancer development.

Statistics

Statistical analyses of tumor data include pair-wise comparisons of tumor incidence in control groups *versus* each treatment group and analysis of exposure related trends. Tumor incidence is the number of animals with a particular neoplasm at a specific anatomic site divided by the number of animals in which that site was examined. If mortality in a dose group is different from that of controls, it is important that these analyses be based on survival-adjusted tumor rates [14]. The reason for this adjustment is that if animals died early from causes other than tumors at the organ of interest, then those animals would not have been on study long enough to provide a contribution of risk equivalent to other groups having better survival. For example, the poly-k quantal response method adjusts site-specific tumor rates within each treatment group for the number of animal years at risk due to differences in intercurrent mortality [21]. Failure to adjust for differences in survival can result in misinterpretations of a true site-specific effect and unreliable estimates of cancer risk.

Although comparisons between the concurrent control group and the exposure groups are the most appropriate for identifying chemical-induced effects, comparisons with historical control data may also be helpful in interpreting whether or not observed differences are treatment-related, e.g., the observation of a small number of rarely occurring tumors in treated animals may not reach statistical significance, yet may exceed historical control rates [22]. For meaningful comparisons, the conditions of the current study must be similar to those in the historical database and diagnostic criteria must be identical. Thus, comparisons must be specific for the species, sex, and strain of animals, the route of exposure, and the diet. A survival-adjusted statistical test for evaluating dose-response trends based on historical control data has been developed to facilitate the interpretation of studies, including those in which exposures are associated with small numbers of rare tumors [23].

Mechanistic Considerations

Results from animal or *in vitro* studies that address molecular and cellular processes involved in tissue responses to environmental compounds (i.e., mechanistic studies) have been used to upgrade or downgrade cancer risk classifications of agents that have inadequate or limited evidence of carcinogenicity in humans. For example, based on mechanistic data, IARC and NTP upgraded ethylene oxide [3, 24] and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) [3, 25] to “known human carcinogens”. In both cases, the evidence of carcinogenicity was limited in humans but sufficient in experimental animals. The upgrading of ethylene oxide was based largely on induction of chromosomal aberrations in peripheral lymphocytes, micronuclei in bone marrow cells, and hemoglobin adducts in exposed workers. Chromosomal alterations are associated with various stages in the multistep process of carcinogenesis. For TCDD, the upgrading was based on data demonstrating that the multisite carcinogenicity of this chemical in experimental animals was due to a mechanism involving activation of the aryl hydrocarbon receptor and studies showing that this receptor is highly conserved across species, and functions similarly in humans and experimental animals. Thus, even though human epidemiological data were at that time not sufficient alone to reach the “known human carcinogen” classification category, these authoritative bodies considered the combination of animal data and mechanistic data sufficient to support the upgraded “weight-of-evidence” conclusions. The term *weight of evidence* is used by the US EPA [4] to reflect evaluations that are “based on the combined strength and coherence of inferences appropriately drawn from all of the available information”.

Similarly, vinyl bromide and vinyl fluoride should be treated as “known human carcinogens” since they act in the same way as vinyl chloride, an agent that has been shown to be causally linked with increased cancer risk in humans. These three chemicals are metabolized by enzymes found in humans to reactive intermediates that form identical promutagenic DNA adducts [26] and experimental carcinogenicity studies have shown that all three chemicals induce multiple tumor types including liver angiosarcomas in rats and mice [27].

Estimating Human Cancer Risk from Animal Tumor Data

Risk assessment provides a systematic approach for characterizing the nature and probability of adverse effects (i.e., health risks) occurring in individuals or populations exposed to hazardous agents and often serves as the basis for risk-management decisions on whether and to what extent human exposure to such agents should be controlled (*see* **Environmental Health Risk**). The National Academy of Sciences (NAS)/National Research Council [28] developed guidelines for the conduct of risk assessments in the US Federal Government. The risk assessment paradigm developed by the NAS consists of four parts: hazard identification, dose–response assessment, exposure assessment, and risk characterization.

Dose–response analyses (*see* **Dose–Response Analysis**) provide a basis for determining *causality* (*see* **Causality/Causation**) from experimental cancer data, evaluating the consistency of mechanistic hypotheses, and estimating low-dose risk. When high-quality human data are available, such as from occupational cohorts, they are preferentially used to estimate human cancer risk at environmental exposure levels and set occupational and environmental exposure standards [4].

When adequate human data are not available, dose–response tumor data from studies in laboratory animals serve as the basis for estimating cancer risks in exposed humans [4]. Site-specific survival-adjusted tumor rates from animal studies are assumed to be relevant for determining human cancer risk unless a mode-of-action has been unequivocally established that contradicts the acceptance of that assumption. A quantitative risk assessment requires conversion of animal doses to equivalent human doses. If a verified physiology based pharmacokinetic model is available for the specific agent, this might be used to describe the internalized dose of the agent or the time-dependent tissue specific concentration of the parent compound or its metabolites. Such a model may be used to characterize internal dose metrics in humans by replacing physiological and biochemical parameters in the animal model with those specific for humans (e.g., breathing volumes, organ sizes, cardiac output, metabolic rate constants, etc.). Computer-based dosimetry models consist of a series of mathematical equations that represent, in quantitative terms, the complex

biological processes that affect the absorption, distribution, metabolism, and elimination of the agent in the intact animal. These models can accommodate parameter values that represent the range and distribution of activities that exist in human populations. Reliable models can provide estimates of tissue dose as a function of duration and frequency of exposure to various environmental exposure levels [29]. However, one must be cautious of assumptions in models that have not been validated because they could lead to inaccurate estimates of tissue dose in specific populations. If a verified dosimetry model is not available, human equivalent exposures are typically obtained by scaling animal doses to humans as a function of body surface area (i.e., body weight^{0.75}) [4].

The next step in the risk assessment process is to use the data on animal cancer to estimate cancer risk at human exposure levels. This is done by fitting empirical dose–response models to the tumor incidence data and an appropriate human dose metric (e.g., a physiology based model estimate of the daily internalized concentrations of reactive metabolites or the rodent scaled equivalent human dose) to extend the dose–response relationship to low doses or to estimate response rates at the low end of the observed dose–response range (i.e., in the 1–10% range of response). Alternatively, a mechanistic-based model may be used if there is sufficient data to establish the mechanism of tumor induction and validated model parameters are available for the key kinetic events associated with that mechanism. For studies with large differences in mortality rates among dose groups, a time-to-tumor model should be used if incidence values were not corrected for survival differences.

By extending the dose–response curve, estimates can be made of extra cancer risk at any dose, including human exposure levels, or estimates can be made of exposure levels that are associated with specific risks (e.g., 1/100, 1/1000, and 1/1 000 000). In their most recent cancer risk assessment guidelines, the US EPA [4] recommends modeling the dose–response data to determine the central estimate of the effective dose associated with 1% (ED₀₁) to 10% (ED₁₀) risk and the associated lower 95% confidence limits on those dose estimates (LED₀₁ or LED₁₀). For example, a modified Weibull model (equation 1) was fit to survival-adjusted tumor data and concentrations of chloroprene or 1,3-butadiene to which mice

were exposed in chronic studies to characterize the shape of the dose–response curve and estimate ED_{10} values and the 95% upper and lower confidence limits [30].

$$P(\text{dose}) = 1 - e^{-(\text{intercept} + \text{scale} \times \text{dose}^{\text{shape}})} \quad (1)$$

$P(\text{dose})$ is the probability of a neoplasm prior to study termination for animals administered a defined dose. The parameters intercept, scale, and shape are estimated *via* maximum-likelihood estimation using a binomial likelihood based on the survival-adjusted tumor data. ED_{10} values obtained from the dose–response curves represent exposure concentrations associated with an excess cancer risk of 10% at each site. A likelihood-ratio test is used to test the hypothesis that the shape parameter equals one. If the shape parameter is equal to one, the dose–response is consistent with a linear model; if the shape parameter is greater than one, the dose–response exhibits sublinear behavior.

A graphical example of this modified Weibull curve with the ED_{10} and the LED_{10} for oral cavity tumors in male rats exposed to chloroprene is given in Figure 1. In this example, the shape parameter is not significantly different from one, so the dose–response curve is fairly linear. The estimated ED_{10} is 21.0 ppm and the lower endpoint of its 95% confidence interval is 6.0 ppm.

From the LED_{10} or the LED_{01} value, corrected for background, a straight line is drawn to the origin (zero risk) for mutagenic carcinogens or chemicals for which the mode-of-action has not been established [4]. Cancer risks at lower exposure levels or doses associated with a specific risk level (e.g., 1/1 000 000 increased lifetime risk) are estimated from the slope of this line (e.g., $0.01/LED_{01}$). These risks can then be compared to age, sex, and race-dependent incidences of specific cancers in the US population reported in the Surveillance, Epidemiology, and End Results data set [31] to determine the relative risk of developing or dying from cancer due to a particular exposure. Relative risk is the incidence of disease in an exposed population divided by the incidence of that disease in the unexposed population. For example, consider that a low-dose extrapolation of an animal carcinogenicity study indicates that a particular exposure level of an agent is associated with an additional leukemia risk of 9/1000 at age 70. The probability of women in the general US population dying from leukemia at that age is 6.6/1000, then the relative risk of dying from leukemia due to that exposure is 2.4. In other words, 70-year old women who received that exposure have 2.4 times the probability of dying from leukemia than do 70-year old women who were unexposed. [The estimated incidence in the unexposed population (P_0) is 6.6/1000, while the estimated

Figure 1 Weibull curve for oral cavity tumors in male rats exposed to chloroprene showing locations of the ED_{10} and LED_{10} [Reproduced from [30]. © Oxford University Press, 1999.]

incidence in the exposed population (P_d) is the background risk (6.6/1000) plus the additional risk associated with exposure (9/1000). Relative risk = $P_d/P_0 = (0.0066 + 0.009)/0.0066 = 2.4$.]

Adjustments to the LED_{10} (or LED_{01}) derived slope factors may be necessary if the data used for the risk assessment do not adequately capture exposures associated with differential susceptibilities. For example, risk levels derived from a study of male workers would not be adequate for female workers if the exposure involves an agent such as 1,3-butadiene that is associated with increased breast cancer risk. To deal with potentially higher lifetime cancer risks due to early life exposures, the US EPA issued a supplementary guidance [32] for adjusting cancer potency estimates for mutagenic carcinogens when data are not available to assess susceptibility from early life exposures to such agents. Based on combined analyses of multiple animal and epidemiological data sets, the US EPA recommends default adjustment factors of 10-fold for exposures occurring before 2 years of age and 3-fold for exposures between 2 and 16 years of age; no adjustments were recommended for exposures occurring after 16 years of age. However, when chemical specific data are available they should be used in preference to default adjustments. Data for carcinogens that act by a nonmutagenic mode-of-action were considered to be too limited and the mechanisms too diverse to support the establishment of default cancer potency adjustment factors for early life exposures to such agents.

Site Concordance

There are several examples in which human cancer sites correspond with one animal species, but not the second species (e.g., hematopoietic cancers are induced by benzene in mice and humans, but not in rats) and there are also examples of site correspondence among rats, mice, and humans [33]. However, because the etiologies of most cancers are not known and the basis for differences in species susceptibility are not fully understood, it would not be prudent to limit considerations of human cancer risk only to organs or tissues in which tumors arise in animal studies.

There are several reasons why site correspondence should not be a requirement for assessing human relevance and causality. First, exposure factors might contribute to differences in sites of tumor induction;

some of these include the route, frequency, duration, intensity, and age at onset of exposure. Exposure conditions are known to affect sites and dose-response for tumor induction in experimental studies. For example, gestational or early childhood exposure is frequently important in tumor induction; consequently, animal or human studies that do not capture these early stages of life may not identify all susceptible organ sites or may underestimate the true carcinogenic risk of the agent. As noted above, for mutagenic agents the US EPA [32] recommends adjustment in risk estimates for studies that did not include childhood exposures. Second, human susceptibility to environmental carcinogens varies for a large number of reasons including genetic factors, health status, diet, lifestyle (e.g., smoking, alcohol consumption), age, and other exposures (e.g., medications, occupational experiences). Because cancer development is the likely result of interactions among environmental factors and individual susceptibility factors, differences in sites of tumor induction among individuals are not unusual for known human carcinogens. For example, although the lung is the most common cancer site among cigarette smokers, many people do not develop lung tumors but instead develop cancers of the bladder, kidney, nasal cavity, lip, esophagus, or pancreas, and some smokers do not develop any diagnosed cancers during their lifetime. Numerous host susceptibility factors could account for lack of site correspondence among individuals in exposed populations or between experimental animals and humans. Because of the much greater genetic diversity in humans compared to strains of laboratory animals, the range of expected human response may include subgroups that are less, equal, or more sensitive than the animal models used in the experimental cancer studies.

Conclusions

Data from properly designed and evaluated studies in experimental animals have been and continue to be reliable sources of information for the identification of potential human health hazards and the estimation of risks in exposed populations. Properly designed animal studies must include: (a) animal models that are sensitive to the endpoints under investigation, (b) detailed characterization of the agent and the administered doses, (c) adequately challenging doses

(MTD) and durations of exposure (at least 2 years for rats and mice) that would allow a reliable determination of whether or not the agent poses a health hazard, (d) sufficient numbers of animals per dose group to have adequate statistical power to detect a true effect, (e) multiple dose groups to allow characterization of dose–response relationships, (f) complete and peer-reviewed histopathological diagnoses, and (g) pairwise comparisons with the control group and analyses of trends based on survival-adjusted tumor rates. Mechanistic information and pharmacokinetic models that have been adequately tested may impact on the characterization of dose–response relationships. Setting occupational or environmental exposure standards based on animal carcinogenicity data provides a prudent public health approach to reduce the burden of cancer in exposed populations. More work is necessary to understand the basis for interindividual differences in susceptibility and to properly establish health-based exposure standards that protect the most vulnerable segments of the general population. Until the etiology of environmentally induced cancers and the basis for human susceptibility are better understood, site correspondence should not be a requirement for judging human relevance and causality.

Canonical Modeling

Assessing Risk in Complex Systems

Under fortuitous conditions quantitative risk assessments may be approached with methods of probability theory. For example, to predict or diagnose the failure risk of a complicated entity such as a nuclear power plant, it is possible to construct fault trees (*see* **Fault Detection and Diagnosis**) or event trees that dissect a complex process into manageable modules (e.g., loss of valve function, a pipe break, a human operator falling asleep) whose failure probabilities can be computed with some reliability from a combination of the physics of the modules, factual knowledge of engineering principles, and expert heuristics [1]. The probabilities of these unit failures become the basis for the computation of all possible conditional probabilities, which are appropriately summed for an assessment of the likelihood of occurrence of the undesired event. The key assumption of this strategy is that all possible component failures and human errors can be quantified with some confidence (*see* **Human Reliability Assessment**). As soon as complicated environmental or health risk scenarios are to be characterized quantitatively, this strategy of dissection into modular risks becomes problematic. The limited applicability of fault tree analysis in environmental and human health has many reasons, but in the end the root cause is usually the enormous complexity of biological systems and the challenge of truly understanding their functioning. For instance, biological systems seldom have a pure tree structure, but instead cycle material back or control themselves with regulatory signals such as feedback inhibition. The challenge of understanding this complexity cannot be mastered with intuition alone but must be addressed with systematic, computational, and mathematical modeling methods, for three reasons.

First, even the simplest biological systems consist of more components than our minds can handle simultaneously. A yeast cell has about 6000 genes, humans have proteins numbering in the hundred thousands. Just naming such vast quantities and tracking them through time and space is difficult. Second, biological components may interact with each other in multitudinous ways, many of which we do not yet understand or even know. The same protein may

have different functional roles; the same gene may be spliced in different ways, thereby coding for different end products; lipids are important building blocks of membranes, but they may also serve as signaling molecules. Third, the interactions within biological systems are seldom linear, with the consequence that increasing an input does not necessarily evoke a similarly increasing output. Following Caesar's motto to divide and conquer (i.e., exploiting the principle of superposition), we are trained to apportion big problems into manageable tasks, and this strategy has been very successful for linear systems. However, for nonlinear systems, subdivision into subsystems becomes problematic when important structural or functional connections are disrupted in the dissection process. Thus, reliable insights into the function of biological systems require integrated representations and nonlinear methods of analysis.

Nature has not provided us with guidelines for how to represent nonlinear phenomena, and the range of possibilities is infinite. It is not even easy to compare objectively two functional representations of simple sigmoidal processes, as they are used as descriptions for growth processes and in high-dose to low-dose extrapolations (*see* **Low-Dose Extrapolation**) in toxicological risk assessment. Indeed, logistic, Hill, arc tangent, and many other functions could essentially give the same data fits [2]. Instead of trying to find "the true" or "the optimal" model, it is often useful to resort to *nonlinear canonical models*, which are based on some suitable type of approximation and have a prescribed mathematical format [3]. Best known among these are Lotka-Volterra models [4] and models of biochemical systems theory (BST [5]). Interestingly, these nonlinear canonical models typically consist of a combination of differentiation, logarithmic transformation, and summation. For instance, each differential equation in a Lotka-Volterra system may be written as the derivative of a logarithmic variable, which equals the weighted sum of the systems variables, while BST models derive from linearization in logarithmic space. Generic advantages of canonical models include the following (*see* [6]):

1. they are mathematically guaranteed to be correct in the vicinity of some nominal state of choice, the so-called *operating point*;
2. many biological observations have been modeled very well;

Figure 1 Generic pathway with inhibition and activation, represented in the manner of BST. Although seemingly simple, the pathway can exhibit qualitatively different responses

3. distinct guidelines are available for constructing and analyzing models;
4. efficient, customized computational tools for analysis, optimization and objective comparisons between competing models have been developed; and
5. they are rich enough in structure to represent essentially all types of smooth processes, no matter how complicated.

Thus, while canonical modeling structures appear at first restrictive, they often have genuine advantages over the infinite possibilities of *ad hoc* models.

As a generic example, consider the deceptively simple pathway in Figure 1 with a typical BST representation shown beneath. Although unbranched, its responses to changes in input X_0 are difficult to foresee. For instance, if $X_0 > 1$, X_1 and X_2 quickly reach a stable steady state. However, as soon as $X_0 < 1$, the steady state becomes unstable, and X_1 and X_2 oscillate in a stable limit cycle around the unstable point. BST models of practical importance and considerable size have been formulated, fully parameterized, and thoroughly analyzed to yield novel insights. Examples include a red blood cell model with close to 100 variables and models of

citric acid, TCA, purine, and sphingolipid metabolism with between 10 and 50 variables. Applications in environmental studies are reviewed in reference [3].

EBERHARD O. VOIT

Case–Control Studies

There are two primary types of nonexperimental studies in epidemiology. The first, the *cohort study* (see **Cohort Studies**) (also called the *follow-up study* or *incidence study*), is a direct analog of the experiment. Different exposure groups are compared, but it is the investigator who selects subjects to observe, and classifies these subjects by exposure status, rather than assigning them to exposure groups. The second, the *incident case–control study*, or simply the *case–control study*, employs an extra step of sampling from the source population for cases. A cohort study includes all persons in the population at risk of becoming a study case. In contrast, a case-control study selects only a sample of those persons, and does so partly on the basis of their final disease status. Thus, by design, a person’s outcome influences their chance of becoming a subject in the case-control study. This extra sampling step can make a case–control study much more efficient than a cohort study of the same population, but it introduces a number of subtleties and avenues for bias that are absent in typical cohort studies.

Conventional wisdom about case–control studies is that they do not yield estimates of effect that are as valid as measures obtained from cohort studies. This thinking may reflect common misunderstandings in conceptualizing case–control studies, but it also reflects concern about quality of exposure information and biases in case or control selection. For example, if exposure information comes from interviews, then cases will have usually reported the exposure information after learning of their diagnosis, which can lead to errors in the responses that are related to the disease (recall bias). While it is true that recall bias does not occur in prospective cohort studies, neither does it occur in all case–control studies. Exposure information that is taken from records whose creation predated disease occurrence will not be subject to recall bias. Similarly, while a cohort study may log information on exposure for an entire source population at the outset of the study, it still requires tracing of subjects to ascertain exposure variation and outcomes, and the success of this tracing may be related to exposure. These concerns are analogous to case–control problems of loss of subjects with unknown exposure and to biased selection

of controls and cases. Each study, whether cohort or case–control, must be considered on its own merits.

Conventional wisdom also holds that cohort studies are useful for evaluating the range of effects related to a single exposure, while case–control studies provide information only about the one disease that afflicts the cases. This thinking conflicts with the idea that case–control studies can be viewed simply as more efficient cohort studies. Just as one can choose to measure more than one disease outcome in a cohort study, it is possible to conduct a set of case–control studies nested within the same population using several disease outcomes as the case series. The case–cohort study (see the section titled “**Case–Cohort Studies**”) is particularly well suited to this task, allowing one control group to be compared with several series of cases. Whether or not the case–cohort design is the form of case–control study that is used, case–control studies do not have to be characterized as being limited with respect to the number of disease outcomes that can be studied.

For diseases that are sufficiently rare, cohort studies become impractical, and case–control studies become the only useful alternative. On the other hand, if exposure is rare, ordinary case–control studies are inefficient, and one must use methods that selectively recruit additional exposed subjects, such as special cohort studies or two-stage designs. If both the exposure and the outcome are rare, two-stage designs may be the only informative option, as they employ oversampling of both exposed and diseased subjects.

Ideally, a case–control study can be conceptualized as a more efficient version of a corresponding cohort study. Under this conceptualization, the cases in the case–control study are the same cases as would ordinarily be included in the cohort study. Rather than including all of the experience of the source population that gave rise to the cases (the study base), as would be the usual practice in a cohort design, controls are selected from the source population. The sampling of controls from the population that gave rise to the cases affords the efficiency gain of a case–control design over a cohort design. The controls provide an estimate of the prevalence of the exposure and covariates in the source population. When controls are selected from members of the population who were at risk for disease at the beginning of the study’s follow-up period, the case–control odds ratio (see **Odds and Odds Ratio**) estimates the risk ratio that would be obtained from a cohort

design. When controls are selected from members of the population who were noncases at the times that each case occurs, or otherwise in proportion to the person-time accumulated by the cohort, the case-control odds ratio estimates the rate ratio that would be obtained from a cohort design. Finally, when controls are selected from members of the population who were noncases at the end of the study's follow-up period, the case-control odds ratio estimates the incidence odds ratio that would be obtained from a cohort design. With each control selection strategy, the odds ratio calculation is the same, but the measure of effect estimated by the odds ratio differs. Study designs that implement each of these control selection paradigms will be discussed after topics that are common to all designs.

Common Elements of Case-Control Studies

In a cohort study, the numerator and denominator of each disease frequency (incidence proportion, incidence rate, or incidence odds) are measured, which requires enumerating the entire population and keeping it under surveillance. A case-control study attempts to observe the population more efficiently by using a control series in place of complete assessment of the denominators of the disease frequencies. The cases in a case-control study should be the same people who would be considered cases in a cohort study of the same population.

Pseudofrequencies and the Odds Ratio

The primary goal for control selection is that the exposure distribution among controls be the same as it is in the source population of cases. The rationale for this goal is that, if it is met, we can use the control series in place of the denominator information in measures of disease frequency to determine the ratio of the disease frequency in exposed people relative to that among unexposed people. This goal will be met if we can sample controls from the source population such that the ratio of the number of exposed controls (B_1) to the total exposed experience of the source population is the same as the ratio of the number of unexposed controls (B_0) to the unexposed experience of the source population, apart from sampling error. For most purposes, this goal need only be followed

within strata defined by the factors that are used for stratification in the analysis, such as factors used for restriction or matching.

Using person-time to illustrate, the goal requires that B_1 has the same ratio to the amount of exposed person-time (T_1) as B_0 has to the amount of unexposed person-time (T_0):

$$\frac{B_1}{T_1} = \frac{B_0}{T_0} \quad (1)$$

Here B_1/T_1 and B_0/T_0 are the control sampling rates – that is, the number of controls selected per unit of person-time. Suppose A_1 exposed cases and A_0 unexposed cases occur over the study period. The exposed and unexposed rates are then

$$I_1 = \frac{A_1}{T_1} \quad (2)$$

and

$$I_0 = \frac{A_0}{T_0} \quad (3)$$

We can use the frequencies of exposed and unexposed controls as substitutes for the actual denominators of the rates to obtain exposure-specific case-control ratios, or *pseudorates*:

$$\text{Pseudorate}_1 = \frac{A_1}{B_1} \quad (4)$$

and

$$\text{Pseudorate}_0 = \frac{A_0}{B_0} \quad (5)$$

These pseudorates have no epidemiologic interpretation by themselves. Suppose, however, that the control sampling rates B_1/T_1 and B_0/T_0 are equal to the same value r , as would be expected if controls are selected independently of exposure. If this common sampling rate r is known, the actual incidence rates can be calculated by simple algebra, since apart from sampling error, B_1/r should equal the amount of exposed person-time in the source population, and B_0/r should equal the amount of unexposed person-time in the source population: $B_1/r = B_1/(B_1/T_1) = T_1$ and $B_0/r = B_0/(B_0/T_0) = T_0$. To get the incidence rates, we need only multiply each pseudorate by the common sampling rate, r .

If the common sampling rate is not known, which is often the case, we can still compare the sizes of

the pseudorates by division. Specifically, if we divide the pseudorate for exposed by the pseudorate for unexposed, we obtain

$$\begin{aligned}\frac{\text{Pseudorate}_1}{\text{Pseudorate}_0} &= \frac{A_1/B_1}{A_0/B_0} = \frac{A_1/[(B_1/T_1)T_1]}{A_0/[(B_0/T_0)T_0]} \\ &= \frac{A_1/(r \cdot T_1)}{A_0/(r \cdot T_0)} = \frac{A_1/T_1}{A_0/T_0}\end{aligned}\quad (6)$$

In other words, the ratio of the pseudorates for the exposed and unexposed is an estimate of the ratio of the incidence rates in the source population, provided that the control sampling rate is independent of exposure. Thus, using the case-control study design, one can estimate the incidence rate ratio in a population without obtaining information on every subject in the population. Similar derivations in the section titled “Variants of the Case-Control Design” show that one can estimate the risk ratio by sampling controls from those at risk for disease at the beginning of the follow-up period (case-cohort design) and that one can estimate the incidence odds ratio by sampling controls from the noncases at the end of the follow-up period (cumulative case-control design). With these designs, the pseudofrequencies correspond to the incidence proportions and incidence odds, respectively, multiplied by common sampling rates.

There is a statistical penalty for using a sample of the denominators, rather than measuring the person-time experience for the entire source population: the precision of the estimates of the incidence rate ratio from a case-control study is less than the precision from a cohort study of the entire population that gave rise to the cases (the source population). Nevertheless, the loss of precision that stems from sampling controls will be small if the number of controls selected per case is large. Furthermore, the loss is balanced by the cost savings of not having to obtain information on everyone in the source population. The cost savings might allow the epidemiologist to enlarge the source population and so obtain more cases, resulting in a better overall estimate of the incidence rate ratio, statistically and otherwise, than would be possible using the same expenditures to conduct a cohort study.

The ratio of the two pseudorates in a case-control study is usually written as A_1B_0/A_0B_1 , and is sometimes called the *cross-product ratio*. The cross-product ratio in a case-control study can be viewed

as the ratio of cases to controls among the exposed subjects (A_1/B_1), divided by the ratio of cases to controls among the unexposed subjects (A_0/B_0). This ratio can also be viewed as the odds of being exposed among cases (A_1/A_0) divided by the odds of being exposed among controls (B_1/B_0), in which case it is termed the *exposure odds ratio*. While either interpretation will give the same result, viewing this odds ratio as the ratio of case-control ratios shows more directly how the control group substitutes for the denominator information in a cohort study and how the ratio of pseudofrequencies gives the same result as the ratio of the incidence rates, incidence proportion, or incidence odds in the source population, if sampling is independent of exposure.

Defining the Source Population

If the cases are a representative sample of all cases in a precisely defined and identified population, and the controls are sampled directly from this source population, the study is said to be *population-based* or a *primary-base* study. For a population-based case-control study, random sampling of controls may be feasible if a population registry exists or can be compiled. When random sampling from the source population of cases is feasible, it is usually the most desirable option.

Random sampling of controls does not necessarily mean that every person should have an equal probability of being selected to be a control. As explained above, if the aim is to estimate the incidence rate ratio, then we would employ longitudinal (density) sampling, in which a person's control selection probability is proportional to the person's time at risk. For example, in a case-control study nested within an occupational cohort, workers on an employee roster will have been followed for varying lengths of time, and a random sampling scheme should reflect this varying time to estimate the incidence rate ratio.

When it is not possible to identify the source population explicitly, simple random sampling is not feasible, and other methods of control selection must be used. Such studies are sometimes called *studies of secondary* bases, because the source population is identified secondarily to the definition of a case-finding mechanism. A secondary source population or *secondary* base is therefore a source population that is defined from (secondary to) a given case series.

Consider a case-control study in which the cases are patients treated for severe psoriasis at the Mayo Clinic. These patients come to the Mayo Clinic from all corners of the world. What is the specific source population that gives rise to these cases? To answer this question, we would have to know exactly who would go to the Mayo Clinic, if he or she had severe psoriasis. We cannot enumerate this source population because many people in it do not know themselves that they would go to the Mayo Clinic for severe psoriasis, unless they actually developed severe psoriasis. This secondary source might be defined as a population spread around the world that constitutes those people who would go to the Mayo Clinic if they developed severe psoriasis. It is this secondary source from which the control series for the study would ideally be drawn. The challenge to the investigator is to apply eligibility criteria to the cases and controls so that there is good correspondence between the controls and this source population. For example, cases of severe psoriasis and controls might be restricted to those in counties within a certain distance of the Mayo Clinic, so that at least a geographic correspondence between the controls and the secondary source population can be assured. This restriction might, however, leave very few cases for study.

Unfortunately, the concept of a secondary base is often tenuously connected to underlying realities, and can be highly ambiguous. For the psoriasis example, whether a person would go to the Mayo Clinic depends on many factors that vary over time, such as whether the person is encouraged to go by their regular physicians and whether the person can afford to go. It is not clear, then, how or even whether one could precisely define the secondary base, let alone draw a sample from it; thus it is not clear one could ensure that controls were members of the base at the time of sampling. We therefore prefer to conceptualize and conduct case-control studies as starting with a well-defined source population, and then identify and recruit cases and controls to represent the disease and exposure experience of that population. When one takes a case series as a starting point instead, it is incumbent upon the investigator to demonstrate that a source population can be operationally defined to allow the study to be recast and evaluated relative to this source. Similar considerations apply when one takes a control series as a starting point, as is sometimes done [1].

Case Selection

Ideally, case selection will amount to a direct sampling of cases within a source population. Therefore, apart from random sampling, all people in the source population who develop the disease of interest are presumed to be included as cases in the case-control study. It is not always necessary, however, to include all cases from the source population. Cases, like controls, can be randomly sampled for inclusion in the case-control study, so long as this sampling is independent of the exposure under study within the strata defined by the stratification factors that are used in the analysis. Of course, if fewer than all cases are sampled, the study precision will be lower in proportion to the sampling fraction.

The cases identified in a single clinic or treated by a single medical practitioner are possible case series for case-control studies. The corresponding source population for the cases treated in a clinic comprises all people who would attend that clinic and would be recorded with the diagnosis of interest, if they had the disease in question. It is important to specify “if they had the disease in question” because clinics serve different populations for different diseases, depending on referral patterns and the reputation of the clinic in specific speciality areas. As noted above, without a precisely identified source population, it may be difficult or impossible to select controls in an unbiased fashion.

Control Selection

The definition of the source population determines the population from which controls are sampled. Ideally, control selection will amount to a direct sampling of people within the source population. On the basis of the principles explained above regarding the role of the control series, many general rules for control selection can be formulated. Two basic rules are as follows: (a) Controls should be selected from the same population – the source population – that gives rise to the study cases. If this rule cannot be followed, there needs to be solid evidence that the population supplying controls has an exposure distribution identical to that of the population that is the source of cases, which is a very stringent demand that is rarely demonstrable. (b) Within strata defined by factors that are used for stratification in the analysis, controls should be selected independently

of their exposure status, in that the sampling rate for controls (r in the above discussion) should not vary with exposure.

If these rules and the corresponding case rule are met, then the ratio of pseudofrequencies will, apart from sampling error, equal the ratio of the corresponding measure of disease frequency in the source population. If the sampling rate is known, then the actual measures of disease frequency can also be calculated [2]. Wacholder *et al.* have elaborated on the principles of control selection in case-control studies [3–5].

When one wishes controls to represent person-time, sampling of the person-time should be constant across exposure levels. This requirement implies that the sampling *probability* of any person as a control should be proportional to the amount of person-time that person spends at risk of disease in the source population. For example, if in the source population one person contributes twice as much person-time during the study period as another person, the first person should have twice the probability of the second of being selected as a control.

This difference in probability of selection is automatically induced by sampling controls at a steady rate per unit time over the period in which cases occur (longitudinal, or density sampling), rather than by sampling all controls at a point in time (such as the start or end of the study). With longitudinal sampling of controls, a population member present for twice as long as another will have twice the chance of being selected.

If the objective of the study is to estimate a risk or rate ratio, it should be possible for a person to be selected as a control and yet remain eligible to become a case, so that person might appear in the study as both a control and a case. This possibility may sound paradoxical or wrong, but is, nevertheless, correct. It corresponds to the fact that in a cohort study, a case contributes to both the numerator and the denominator of the estimated incidence. If the controls are intended to represent person-time and are selected longitudinally, similar arguments show that a person selected as a control should remain eligible to be selected as a control again, and thus might be included in the analysis repeatedly as a control [6, 7].

Common Fallacies in Control Selection

In cohort studies, the study population is restricted to people at risk for the disease. Because they

viewed case-control studies as if they were cohort studies done backwards, some authors argued that case-control studies ought to be restricted to those at risk for exposure (i.e., those with exposure opportunity). Excluding sterile women from a case-control study of an adverse effect of oral contraceptives and matching for duration of employment in an occupational study are examples of attempts to control for exposure opportunity. Such restrictions do not directly address validity issues, and can ultimately harm study precision by reducing the number of unexposed subjects available for study [8]. If the factor used for restriction (e.g., sterility) is unrelated to the disease, it will not be a confounder, and hence the restriction will yield no benefit to the validity of the estimate of effect. Furthermore, if the restriction reduces the study size, the precision of the estimate of effect will be reduced.

Another principle sometimes used in cohort studies is that the study cohort should be “clean” at start of follow-up, including only people who have never had the disease. Misapplying this principle to case-control design suggests that the control group ought to be “clean”, including only people who are healthy, for example. Illness arising after the start of the follow-up period is not reason to exclude subjects from a cohort analysis, and such exclusion can lead to bias. Similarly, controls with illness that arose after exposure should not be removed from the control series. Nonetheless, in studies of the relation between cigarette smoking and colorectal cancer, certain authors recommended that the control group should exclude people with colon polyps, because colon polyps are associated with smoking and are precursors of colorectal cancer [9]. But such exclusion reduces the prevalence of the exposure in the controls below that in the actual source population of cases, and hence biases the effect estimates upward [10].

Sources for Control Series

The methods suggested below for control sampling apply when the source population cannot be explicitly enumerated, so random sampling is not possible. These methods should only be implemented subject to the reservations about secondary bases described above.

Neighborhood Controls. If the source population cannot be enumerated, it may be possible to select

controls through sampling of residences. This method is not straightforward. Usually, a geographic roster of residences is not available, so a scheme must be devised to sample residences without enumerating them all. For convenience, investigators may sample controls who are individually matched to cases from the same neighborhood. That is, after a case is identified, one or more controls residing in the same neighborhood as that case are identified and recruited into the study. If neighborhood is related to exposure, the matching should be taken into account in the analysis.

Neighborhood controls are often used when the cases are recruited from a convenient source, such as a clinic or hospital. Such usage can introduce bias, however, for the neighbors selected as controls may not be in the source population of the cases. For example, if the cases are from a particular hospital, neighborhood controls may include people who would not have been treated at the same hospital had they developed the disease. If being treated at the hospital from which cases are identified is related to the exposure under study, then using neighborhood controls would introduce a bias. For any given study, the suitability of using neighborhood controls needs to be evaluated with regard to the study variables on which the research focuses.

Hospital- or Clinic-Based Controls. As noted above, the source population for hospital- or clinic-based case-control studies is not often identifiable, since it represents a group of people who would be treated in a given clinic or hospital if they developed the disease in question. In such situations, a random sample of the general population will not necessarily correspond to a random sample of the source population. If the hospitals or clinics that provide the cases for the study only treat a small proportion of cases in the geographic area, then referral patterns to the hospital or clinic are important to take into account in the sampling of controls. For these studies, a control series comprising patients from the same hospitals or clinics as the cases may provide a less biased estimate of effect than general-population controls (such as those obtained from case neighborhoods or by random-digit dialing). The source population does not correspond to the population of the geographic area, but only to the people who would seek treatment at the hospital or clinic were they to develop the disease under study. While the latter population may

be difficult or impossible to enumerate or even define very clearly, it seems reasonable to expect that other hospital or clinic patients will represent this source population better than general-population controls. The major problem with any nonrandom sampling of controls is the possibility that they are not selected independently of exposure in the source population. Patients hospitalized with other diseases, for example, may be unrepresentative of the exposure distribution in the source population either because exposure is associated with hospitalization, or because the exposure is associated with the other diseases, or both. For example, suppose the study aims to evaluate the relation between tobacco smoking and leukemia using hospitalized cases. If controls are people hospitalized with other conditions, many of them will have been hospitalized for conditions associated with smoking. A variety of other cancers, as well as cardiovascular diseases and respiratory diseases, are related to smoking. Thus, a control series of people hospitalized for diseases other than leukemia would include a higher proportion of smokers than would the source population of the leukemia cases.

Limiting the diagnoses for controls to conditions for which there is no prior indication of an association with the exposure improves the control series. For example, in a study of smoking and hospitalized leukemia cases, one could exclude from the control series anyone who was hospitalized with a disease known to be related to smoking. Such an exclusion policy may exclude most of the potential controls, since cardiovascular disease by itself would represent a large proportion of hospitalized patients. Nevertheless, even a few common diagnostic categories should suffice to find enough control subjects, so that the exclusions will not harm the study by limiting the size of the control series. Indeed, in limiting the scope of eligibility criteria, it is reasonable to exclude categories of potential controls even on the suspicion that a given category might be related to the exposure. If wrong, the cost of the exclusion is that the control series becomes more homogeneous with respect to diagnosis and perhaps a little smaller. But if right, then the exclusion is important to the ultimate validity of the study.

On the other hand, an investigator can rarely be sure that an exposure is not related to a disease or to hospitalization for a specific diagnosis. Consequently, it would be imprudent to use only a single diagnostic category as a source of controls. Using a variety of

diagnoses has the advantage of potentially diluting the biasing effects of including a specific diagnostic group that is related to the exposure.

Excluding a diagnostic category from the list of eligibility criteria for identifying controls is intended simply to improve the representativeness of the control series with respect to the source population. Such an exclusion criterion does not imply that there should be exclusions based on disease history [11]. For example, in a case-control study of smoking and hospitalized leukemia patients, one might use hospitalized controls but exclude any who are hospitalized because of cardiovascular disease. This exclusion criterion for controls does not imply that leukemia cases who have had cardiovascular disease should be excluded; only if the cardiovascular disease was a cause of the hospitalization, should the case be excluded. For controls, the exclusion criterion should only apply to the cause of the hospitalization used to identify the study subject. A person who was hospitalized because of a traumatic injury and who is thus eligible to be a control would not be excluded if he or she had previously been hospitalized for cardiovascular disease. The source population includes people who have had cardiovascular disease, and they should be included in the control series. Excluding such people would lead to an underrepresentation of smoking relative to the source population and produce an upward bias in the effect estimates.

If exposure directly affects hospitalization (for example, if the decision to hospitalize is in part based on exposure history), the resulting bias cannot be remedied without knowing the hospitalization rates, even if the exposure is unrelated to the study disease or the control diseases. This problem was in fact one of the first problems of hospital-based studies to receive detailed analysis [12], and is often called *Berksonian bias*.

Other Diseases. In many settings, especially in populations with established disease registries or insurance-claims databases, it may be most convenient to choose controls from people who are diagnosed with other diseases. The considerations needed for valid control selection from other diagnoses parallel those just discussed for hospital controls. It is essential to exclude any diagnoses known or suspected to be related to exposure, and better still to include only diagnoses for which there is some evidence to indicate they are unrelated to exposure.

These exclusion and inclusion criteria apply only to the diagnosis that brought the person into the registry or database from which controls are selected. The history of an exposure-related disease should not be a basis for exclusion. If, however, the exposure directly affects the chance of entering the registry or database, the study will be subject to the Berksonian bias mentioned earlier for hospital studies.

Other Considerations for Subject Selection

Representativeness. Some textbooks have stressed the need for representativeness in the selection of cases and controls. The advice has been that cases should be representative of all people with the disease and that controls should be representative of the entire nondiseased population. Such advice can be misleading. A case-control study may be restricted to any type of case that may be of interest: female cases, old cases, severely ill cases, cases that died soon after disease onset, mild cases, cases from Philadelphia, cases among factory workers, and so on. In none of these examples would the cases be representative of all people with the disease, yet, in each one, perfectly valid case-control studies are possible [13]. The definition of a case can be virtually anything that the investigator wishes.

Ordinarily, controls should represent the source population for cases, rather than the entire nondiseased population. The latter may differ vastly from the source population for the cases by age, race, sex (e.g., if the cases come from a Veterans administration hospital), socioeconomic status, occupation, and so on – including the exposure of interest. One of the reasons for emphasizing the similarities rather than the differences between cohort and case-control studies is that numerous principles apply to both types of study, but are more evident in the context of cohort studies. In particular, many principles relating to subject selection apply identically to both types of study. For example, it is widely appreciated that cohort studies can be based on special cohorts, rather than on the general population. It follows that case-control studies can be conducted by sampling cases and controls from within those special cohorts. The resulting controls should represent the distribution of exposure across those cohorts, rather than the general population, reflecting the more general rule that controls should represent the source population of the cases in the study, not the general population.

Comparability of Information. Some authors have recommended that information obtained about cases and controls should be of comparable or equal accuracy, to ensure nondifferentiality (equal distribution) of measurement errors [3]. The rationale for this principle is the notion that nondifferential measurement error biases the observed association toward the null, and so will not generate a spurious association, and that bias in studies with nondifferential error is more predictable than in studies with differential error.

The comparability-of-information principle is often used to guide selection of controls and collection of data. For example, it is the basis for using proxy respondents instead of direct interviews for living controls, whenever case information is obtained from proxy respondents. Unfortunately, in most settings, the arguments for the principle are logically unsound. For example, in a study that used proxy respondents for cases, use of proxy respondents for the controls might lead to greater bias than use of direct interviews with controls, even if measurement error is differential. The comparability-of-information principle is therefore applicable only under very limited conditions. In particular, it would seem to be useful only when confounders and effect modifiers are measured with negligible error, and when measurement error is reduced by using comparable sources of information. Otherwise, the effect of forcing comparability of information may be as unpredictable as the effect of using noncomparable information.

Timing of Classification and Diagnosis. The principles for classifying persons, cases, and person-time units in cohort studies according to exposure status also apply to cases and controls in case-control studies. If the controls are intended to represent person-time (rather than persons) in the source population, one should apply principles for classifying person-time to the classification of controls. In particular, principles of person-time classification lead to the rule that controls should be classified by their exposure status as of their selection time. Exposures accrued after that time should be ignored. The rule necessitates that information (such as exposure history) be obtained in a manner that allows one to ignore exposures accrued after the selection time. In a similar manner, cases should be classified as of time of diagnosis or disease onset, accounting for any built-in lag periods or induction-period hypotheses.

Variants of the Case-Control Design

Nested Case-Control Studies

Epidemiologists sometimes refer to specific case-control studies as *nested* case-control studies when the population within which the study is conducted is a fully enumerated cohort, which allows formal random sampling of cases and controls to be carried out. The term is usually used in reference to a case-control study conducted within a cohort study, in which further information (perhaps from expensive tests) is obtained on most or all cases, but for economy is obtained from only a fraction of the remaining cohort members (the controls). Nonetheless, many population-based case-control studies can be thought of as nested within an enumerated source population.

Case-Cohort Studies

The *case-cohort study* is a case-control study in which the source population is a cohort, and every person in this cohort has an equal chance of being included in the study as a control, regardless of how much time that person has contributed to the person-time experience of the cohort or whether the person developed the study disease. This is a logical way to conduct a case-control study when the effect measure of interest is the ratio of incidence proportions rather than a rate ratio, as is common in perinatal studies. The average risk (or incidence proportion) of falling ill during a specified period may be written as

$$R_1 = \frac{A_1}{N_1} \quad (7)$$

for the exposed subcohort and

$$R_0 = \frac{A_0}{N_0} \quad (8)$$

for the unexposed subcohort, where R_1 and R_0 are the incidence proportions among the exposed and unexposed, respectively, and N_1 and N_0 are the initial sizes of the exposed and unexposed subcohorts. (This discussion applies equally well to exposure variables with several levels, but, for simplicity, we consider only a dichotomous exposure.) Controls should be selected such that the exposure distribution among them will estimate without bias the exposure distribution in the source population. In a case-cohort study,

the distribution we wish to estimate is among the $N_1 + N_0$ cohort members, not among their person-time experience [14–16].

The objective is to select controls from the source cohort such that the ratio of the number of exposed controls (B_1) to the number of exposed cohort members (N_1) is the same as the ratio of the number of unexposed controls (B_0) to the number of unexposed cohort members (N_0), apart from sampling error:

$$\frac{B_1}{N_1} = \frac{B_0}{N_0} \quad (9)$$

Here, B_1/N_1 and B_0/N_0 are the control sampling fractions (the number of controls selected per cohort member). Apart from random error, these sampling fractions will be equal if controls have been selected independently of exposure.

We can use the frequencies of exposed and unexposed controls as substitutes for the actual denominators of the incidence proportions to obtain “pseudorisks”:

$$\text{Pseudorisk}_1 = \frac{A_1}{B_1} \quad (10)$$

and

$$\text{Pseudorisk}_0 = \frac{A_0}{B_0} \quad (11)$$

These pseudorisks have no epidemiologic interpretation by themselves. Suppose, however, that the control sampling fractions are equal to the same fraction, f . Then, apart from sampling error, B_1/f should equal N_1 , the size of the exposed subcohort; and B_0/f should equal N_0 , the size of the unexposed subcohort: $B_1/f = B_1/(B_1/N_1) = N_1$ and $B_0/f = B_0/(B_0/N_0) = N_0$. Thus, to get the incidence proportions, we need only multiply each pseudorisk by the common sampling fraction, f . If this fraction is not known, we can still compare the sizes of the pseudorisks by division:

$$\begin{aligned} \frac{\text{Pseudorisk}_1}{\text{Pseudorisk}_0} &= \frac{A_1/B_1}{A_0/B_0} = \frac{A_1/[(B_1/N_1)N_1]}{A_0/[(B_0/N_0)N_0]} \\ &= \frac{A_1/fN_1}{A_0/fN_0} = \frac{A_1/N_1}{A_0/N_0} \end{aligned} \quad (12)$$

In other words, the ratio of pseudorisks is an estimate of the ratio of incidence proportions (risk ratio) in the source cohort if control sampling

is independent of exposure. Thus, using a case-cohort design, one can estimate the risk ratio in a cohort without obtaining information on every cohort member.

Thus far, we have implicitly assumed that there is no loss to follow-up or competing risks in the underlying cohort. If there are such problems, it is still possible to estimate risk or rate ratios from a case-cohort study, provided that we have data on the time spent at risk by the sampled subjects or we use certain sampling modifications [17]. These procedures require the usual assumptions for rate-ratio estimation in cohort studies, namely, that loss to follow-up and competing risks are either not associated with exposure or not associated with disease risk.

An advantage of the case-cohort design is that it facilitates conduct of a set of case-control studies from a single cohort, all of which use the same control group. Just as one can measure the incidence rate of a variety of diseases within a single cohort, one can conduct a set of simultaneous case-control studies using a single control group. A sample from the cohort is the control group needed to compare with any number of case groups. If matched controls are selected from people at risk at the time a case occurs (as in risk-set sampling, which is described in the section titled “Density Case-Control Studies”), the control series must be tailored to a specific group of cases. To have a single control series serve many case groups, another sampling scheme must be used. The case-cohort approach is a good choice in such a situation.

Wacholder has discussed the advantages and disadvantages of the case-cohort design relative to the usual type of case-control study [18]. One point to note is that, because of the overlap of membership in the case and control groups (controls who are selected may also develop disease and enter the study as cases), one will need to select more controls in a case-cohort study than in an ordinary case-control study with the same number of cases, if one is to achieve the same amount of statistical precision. Extra controls are needed because the statistical precision of a study is strongly determined by the numbers of distinct cases and noncases. Thus, if 20% of the source cohort members will become cases, and all cases will be included in the study, one will have to select 1.25 times as many controls as cases in a case-cohort study to insure that there will be as many

controls who never become cases in the study. On average, only 80% of the controls in such a situation will remain noncases; the other 20% will become cases. Of course, if the disease is uncommon, the number of extra controls needed for a case-cohort study will be small.

Density Case-Control Studies

Earlier, we described how case-control odds ratios will estimate rate ratios if the control series is selected so that the ratio of the person-time denominators T_1/T_0 is validly estimated by the ratio of exposed to unexposed controls B_1/B_0 . That is, to estimate rate ratios, controls should be selected so that the exposure distribution among them is, apart from random error, the same as it is among the person-time in the source population. Such control selection is called *density sampling* because it provides for estimation of relations among incidence rates, which have been called *incidence densities*.

If a subject's exposure may vary over time, then a case's exposure history is evaluated up to the time the disease occurred. A control's exposure history is evaluated up to an analogous index time, usually taken as the time of sampling; exposure after the time of selection must be ignored. This rule helps ensure that the number of exposed and unexposed controls will be in proportion to the amount of exposed and unexposed person-time in the source population.

The time during which a subject is eligible to be a control should be the time in which that person is also eligible to become a case, should the disease occur. Thus, a person in whom the disease has already developed or who has died is no longer eligible to be selected as a control. This rule corresponds to the treatment of subjects in cohort studies. Every case that is tallied in the numerator of a cohort study contributes to the denominator of the rate until the time that the person becomes a case, when the contribution to the denominator ceases. One way to implement this rule is to choose controls from the set of people in the source population who are at risk of becoming a case at the time that the case is diagnosed. This set is sometimes referred to as the *risk set* for the case, and this type of control sampling is sometimes called *risk-set sampling*. Controls sampled in this manner are matched to the case with respect to sampling time; thus, if time is related to exposure, the resulting data should be analyzed as matched data

[19]. It is also possible to conduct unmatched density sampling using probability sampling methods if one knows the time interval at risk for each population member. One then selects a control by sampling members with probability proportional to time at risk, and then randomly samples a time to measure exposure within the interval at risk.

As mentioned earlier, a person selected as a control, and who remains in the study population at risk after selection should remain eligible to be selected once again as a control. Thus, although unlikely in typical studies, the same person may appear in the control group two or more times. Note, however, that including the same person at different times does not necessarily lead to exposure (or confounder) information being repeated, because this information may change with time. For example, in a case-control study of an acute epidemic of intestinal illness, one might ask about food ingested within the previous day or days. If a contaminated food item was a cause of the illness for some cases, then the exposure status of a case or control chosen 5 days into the study might well differ from what it would have been 2 days into the study when the subject might also have been included as a control.

Cumulative ("Epidemic") Case-Control Studies

In some research settings, case-control studies may address a risk that ends before subject selection begins. For example, a case-control study of an epidemic of diarrheal illness after a social gathering may begin after all the potential cases have occurred (because the maximum induction time has elapsed). In such a situation, an investigator might select controls from that portion of the population that remains after eliminating the accumulated cases; that is, one selects controls from among noncases (those who remain noncases at the end of the epidemic follow-up).

Suppose that the source population is a cohort and that a fraction f of both exposed and unexposed noncases are selected to be controls. Then the ratio of pseudofrequencies will be

$$\frac{A_1/B_1}{A_0/B_0} = \frac{A_1/f(N_1 - A_1)}{A_0/f(N_0 - A_0)} = \frac{A_1/(N_1 - A_1)}{A_0/(N_0 - A_0)} \quad (13)$$

which is the incidence odds ratio for the cohort. The latter ratio will provide a reasonable approximation to the rate ratio, provided that the proportions falling ill

in each exposure group during the risk period are low, that is, less than about 20%, and that the prevalence of exposure remains reasonably steady during the study period. If the investigator prefers to estimate the risk ratio rather than the incidence rate ratio, the study odds ratio can still be used [20], but the accuracy of this approximation is only about half as good as that of the odds ratio approximation to the rate ratio [21]. The use of this approximation in the cumulative design is the basis for the common and mistaken notion that a rare-disease assumption is needed to estimate risk ratios in all case-control studies.

Prior to the 1970s, the standard conceptualization of case-control studies involved the cumulative design, in which controls are selected from noncases at the end of a follow-up period. As discussed by numerous authors [19, 22, 23], density designs and case-cohort designs have several advantages outside of the acute epidemic setting, including potentially much less sensitivity to bias from exposure-related loss to follow-up.

Case-Specular and Case-Crossover Studies

When the exposure under study is defined by proximity to an environmental source (e.g., a power line), it may be possible to construct a *specular* (hypothetical) control for each case, by conducting a “thought experiment”. Either the case or the exposure source is imaginarily moved to another location that would be equally likely were there no exposure effect; the case exposure level under this hypothetical configuration is then treated as the (matched) “control” exposure for the case [24]. When the specular control arises by examining the exposure experience of the case outside of the time in which exposure could be related to disease occurrence, the result is called a *case-crossover study*.

The classic *crossover* study is a type of experiment in which two (or more) treatments are compared, as in any experimental study. In a crossover study, however, each subject receives both treatments, with one following the other. Preferably, the order in which the two treatments are applied is randomly chosen for each subject. Enough time should be allocated between the two administrations so that the effect of each treatment can be measured and can subside before the other treatment is given. A persistent effect of the first intervention is called a *carryover effect*. A crossover study is only valid

to study treatments for which effects occur within a short induction period and do not persist, i.e., carryover effects must be absent, so that the effect of the second intervention is not intermingled with the effect of the first.

The *case-crossover* study is a case-control analogue of the crossover study [25]. For each case, one or more predisease or postdisease time periods are selected as matched “control” periods for the case. The exposure status of the case at the time of the disease onset is compared with the distribution of exposure status for that same person in the control periods. Such a comparison depends on the assumption that neither exposure nor confounders change with time in a systematic way.

Only a limited set of research topics are amenable to the case-crossover design. The exposure must vary over time within individuals, rather than stay constant. If the exposure does not vary within a person, then there is no basis for comparing exposed and unexposed time periods of risk within the person. Like the crossover study, the exposure must also have a short induction time and a transient effect; otherwise, exposures in the distant past could be the cause of a recent disease onset (a carryover effect).

Maclure [25] used the case-crossover design to study the effect of sexual activity on incident myocardial infarction. This topic is well suited to a case-crossover design because the exposure is intermittent and is presumed to have a short induction period for the hypothesized effect. Any increase in risk for a myocardial infarction from sexual activity is presumed to be confined to a short time following the activity. A myocardial infarction is an outcome well suited to this type of study because it is thought to be triggered by events close in time.

Each case in a case-crossover study is automatically matched with its control on all characteristics (e.g., sex and birth date) that do not change within individuals. A matched analysis of case-crossover data automatically adjusts for all such fixed confounders, whether or not they are measured. Control for measured time-varying confounders is possible using modeling methods for matched data. It is also possible to adjust case-crossover estimates for bias owing to time trends in exposure through use of longitudinal data from a nondiseased control group (case-time controls) [26]. Nonetheless, these trend adjustments themselves depend on additional

no-confounding assumptions and may introduce bias if those assumptions are not met [27].

Two-Stage Sampling

Another variant of the case-control study uses two-stage or two-phase sampling [28, 29]. In this type of study, the control series comprises a relatively large number of people (possibly everyone in the source population), from whom exposure information or perhaps some limited amount of information on other relevant variables is obtained. Then, for only a subsample of the controls, more detailed information is obtained on exposure or on other study variables that may need to be controlled in the analysis. More detailed information may also be limited to a subsample of cases. This two-stage approach is useful when it is relatively inexpensive to obtain the exposure information (e.g., by telephone interview), but the covariate information is more expensive to obtain (say, by laboratory analysis). It is also useful when exposure information already has been collected on the entire population (e.g., job histories for an occupational cohort), but covariate information is needed (e.g., genotype). This situation arises in cohort studies when more information is required than was gathered at baseline. This type of study requires special analytic methods to take full advantage of the information collected at both stages.

Case-Control Studies with Prevalent Cases

Case-control studies are sometimes based on prevalent cases rather than incident cases. When it is impractical to include only incident cases, it may still be possible to select existing cases of illness at a point in time. If the prevalence odds ratio in the population is equal to the incidence rate ratio, then the odds ratio from a case-control study based on prevalent cases can unbiasedly estimate the rate ratio. The conditions required for the prevalence odds ratio to equal the rate ratio are very strong, however, and a simple relation does not exist for age-specific ratios. If exposure is associated with duration of illness or migration out of the prevalence pool, then a case-control study based on prevalent cases cannot by itself distinguish exposure effects on disease incidence from the exposure association with disease duration or migration, unless the strengths of the latter associations are known. If the size of the exposed

or the unexposed population changes with time or there is migration into the prevalence pool, the prevalence odds ratio may be further removed from the rate ratio. Consequently, it is always preferable to select incident rather than prevalent cases when studying disease etiology.

Prevalent cases are usually drawn in studies of congenital malformations. In such studies, cases ascertained at birth are prevalent because they have survived with the malformation from the time of its occurrence until birth. It would be etiologically more useful to ascertain all incident cases, including affected abortuses that do not survive until birth. Many of these, however, do not survive until ascertainment is feasible, and thus it is virtually inevitable that case-control studies of congenital malformations are based on prevalent cases. In this example, the source population comprises all conceptuses, and miscarriage and induced abortion represent emigration before the ascertainment date. Although an exposure will not affect duration of a malformation, it may very well affect risks of miscarriage and abortion.

Other situations in which prevalent cases are commonly used are studies of chronic conditions with ill-defined onset times and limited effects on mortality, such as obesity and multiple sclerosis, and studies of health services utilization.

Conclusion

Epidemiologic research employs a range of study designs, including both experimental and nonexperimental studies. Among nonexperimental studies, cohort designs are sometimes thought to be inherently less susceptible to bias than case-control designs. Nonetheless, most of the biases that are associated with case-control studies are not inherent to the design, nor are cohort studies immune from bias. For example, recall bias will not occur in case-control study when exposure comes from records taken before disease onset, and selection bias can occur in cohort studies that suffer from loss to follow-up. No epidemiologic study is perfect, and this caution applies to cohort studies as well as case-control studies. A clear understanding of the principles of study design is essential for valid study design, conduct, and analysis, and for proper interpretation of results, regardless of the design.

Causal Diagrams

From their inception in the early twentieth century, causal systems models (more commonly known as *structural-equations models*) have been accompanied by graphical representations or path diagrams that provide compact summaries of qualitative assumptions made by the models. Figure 1 provides a graph that would correspond to any system of five equations encoding these assumptions:

1. independence of A and B
2. direct dependence of C on A and B
3. direct dependence of E on A and C
4. direct dependence of F on C and
5. direct dependence of D on B , C , and E .

The interpretation of “direct dependence” was kept rather informal and usually conveyed by causal intuition, for example, that the entire influence of A on F is “mediated” by C .

By the 1980s it was recognized that these diagrams could be reinterpreted formally as probability models, enabling use of graph theory in probabilistic inference, and allowing easy deduction of independence conditions implied by the assumptions [1]. By the 1990s it was further recognized that these diagrams could also be used as a formal tool for causal inference [2–5] and for illustrating sources of bias and their remedy in epidemiological research [6–15]. Given that the graph is correct, one can analyze whether the causal effects of interest (target effects or causal estimands) can be estimated from available data, or what additional observations are needed to validly estimate those effects. One can also see from the graph which variables should and should not be conditioned on (“controlled”) in order to estimate a given effect.

This article gives an overview of the following: (a) components of causal graph theory; (b) probability interpretations of graphical models; and (c) methodological implications of the causal and probability structures encoded in the graph, such as sources of bias and the data needed for their control. See **Causality/Causation** for a discussion of definitions of causation and statistical models for causal inference.

Basics of Graph Theory

As a befitting and well-developed mathematical topic, graph theory has an extensive terminology that once mastered provides access to a number of elegant results that may be used to model any system of relations. The term *dependence* in a graph, usually represented by connectivity, may refer to mathematical, causal, or statistical dependencies. The connectives joining variables in the graph are called *arcs*, *edge*, or *links*, and the variables are also called *nodes* or *vertices*. Two variables connected by an arc are *adjacent* or *neighbors* and arcs that meet at a variable are also adjacent. If the arc is an arrow, the tail (starting) variable is the *parent* and the head (ending) variable is the *child*. In causal diagrams, an arrow represents a “direct effect” of the parent on the child, although this effect is direct only relative to a certain level of abstraction, in that the graph omits any variables that might mediate the effect.

A variable that has no parent (such as A and B in Figure 1) is *exogenous* or *external*, or a *root* or *source* node, and is determined only by forces outside the graph; otherwise it is *endogenous* or *internal*. A variable with no children (such as D in Figure 1) is a *sink* or *terminal node*. The set of all parents of a variable X (all variables at the tail of an arrow pointing into X) is denoted $\text{pa}[X]$; in Figure 1, $\text{pa}[D] = \{B, C, E\}$.

A *path* or *chain* is a sequence of adjacent arcs. A *directed path* is a path traced out entirely along arrows tail-to-head. If there is a directed path from X to Y , X is an *ancestor* of Y and Y is a *descendant* of X . In causal diagrams, directed paths represent causal pathways from the starting variable to the ending variable; a variable is thus often called a *cause of its descendants* and an *effect of its ancestors*. In a *directed* graph the only arcs are arrows, and in an *acyclic* graph there is no feedback loop (directed path from a variable back to itself). Therefore, a directed acyclic graph (DAG) is a graph with only arrows for edges and no feedback loops (i.e., no variable is its own ancestor or its own descendant). A causal DAG represents a complete causal structure, in that all sources of dependence are explained by causal links; in particular, all common (shared) causes of variables in the graph are also in the graph.

A variable *intercepts* a path if it is in the path (but not at the ends); similarly, a set of variables S intercepts a path if it contains any variable intercepting

Figure 1 Example of causal diagram

the path. Variables that intercept directed paths are *intermediates* or *mediators* on the pathway. A variable is a *collider* on the path if the path enters and leaves the variable *via* arrowheads (a term suggested by the collision of causal forces at the variable). Note that being a collider is relative to a path; for example in Figure 1, C is a collider on the path $A \rightarrow C \leftarrow B \rightarrow D$ and a noncollider on the path $A \rightarrow C \rightarrow D$. Nonetheless, it is common to refer to a variable as a collider if it is a collider along any path (i.e., if it has more than one parent). A path is *open* or *unblocked* at noncolliders and *closed* or *blocked* at colliders; hence a path with no collider (like $E \leftarrow C \leftarrow B \rightarrow D$) is *open* or *active*, while a path with a collider (like $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$) is *closed* or *inactive*.

Some of the most important constraints imposed by a graphical model correspond to independencies arising from absence of open paths; e.g., absence of an open path from A to B in Figure 1 constrains A and B to be marginally independent (i.e., independent if no stratification is done). Nonetheless, the converse does not hold; i.e., presence of an open path allows but does not imply dependency. Independence may arise through cancellation of dependencies; as a consequence, even adjacent variables may be marginally independent; e.g., in Figure 1, A and E could be marginally independent if the dependencies through paths $A \rightarrow E$ and $A \rightarrow C \rightarrow E$ cancelled each other. The assumption of faithfulness, discussed below, is designed to exclude such possibilities.

Some authors use a bidirectional arc (two-headed arrow, $\leftrightarrow$) to represent the assumption that two variables share ancestors that are not shown in the graph; $A \leftrightarrow B$ then means that there is an unspecified variable U with directed paths to both A and B (e.g., $A \leftarrow U \rightarrow B$). Certain authors use $A \leftrightarrow B$ less specifically, however, in the way $A - B$ is used here to designate the presence of nondirected open paths

between A and B that are not intercepted by any variable in the graph.

Control: Manipulation versus Conditioning

The word *control* is used throughout science, but with a variety of meanings that are important to distinguish. In experimental research, to control a variable C usually means to manipulate or set its value. In observational studies, however, to control C (or more precisely, to control for C) more often means to condition on C , usually by stratifying on C or by entering C in a regression model. The two processes are very different physically and have very different representations and implications.

If a variable X is influenced by a researcher, the DAG would need an ancestor R of X to represent this influence. In the classical experimental case in which the researcher alone determines X , R , and X would be identical. In human trials, however, R more often represents just an *intention* to treat (with the assigned level of X), leaving X to be influenced by other factors that affect compliance with the assigned treatment R . In either case, R might be affected by other variables in the graph. For example, if the researcher uses age to determine assignments (an age-biased allocation), age would be a parent of R . Ordinarily, however, R would be exogenous as when R represents a randomized allocation.

In contrast, by definition in an observational study there is no such variable R representing the researcher's influence on X , and conditioning is substituted for experimental control. Conditioning on a variable C in a DAG can be represented by creating a new graph from the original graph to represent constraints on relations within levels (strata) of C implied by the constraints imposed by the original graph. This conditional graph can be found by the following sequence of operations [6], sometimes called *graphical moralization*.

1. If C is a collider, join ("marry") all pairs of parents of C by undirected arcs (here a dashed line will be used).
2. Similarly, if A is an ancestor of C and a collider, join all pairs of parents of A by undirected arcs.
3. Erase C and all arcs connecting C to other variables.

Figure 2 shows the graph derived from conditioning on C in Figure 1: the parents A and B of C are

Figure 2 Graph derived from Figure 1 after conditioning on C

joined by an undirected arc, while C and all its arcs are gone. Figure 3 shows the result of conditioning on $F:C$ is an ancestral collider of F and so, again its parents A and B are joined, but only F and its single arc are erased. Note that, because of the undirected arcs, neither figure is a DAG.

Operations 1 and 2 reflect that if C depends on A and B through distinct pathways, the marginal dependence of A on B will not equal the dependence of A on B stratified on C (apart from special cases). To illustrate, suppose A and B are binary indicators (i.e., equal to 1 or 0), marginally independent, and $C = A + B$. Then among persons with $C = 1$, some will have $A = 1, B = 0$ and some will have $A = 0, B = 1$ (because other combinations produce $C \neq 1$). Thus when $C = 1$, A and B will exhibit perfect negative dependence: $A = 1 - B$ for all persons with $C = 1$.

Conditioning on a variable C closes open paths that pass through C . Conversely, conditioning on C opens paths that were blocked only at C or an ancestral collider A . In particular, conditioning on a variable may open a path even if it is not on the path, as with F in Figures 1 and 3. Thus the consequences of conditioning on C are often illustrated in the original (unconditional) graph by drawing a circle around C to denote the conditioning, then defining a path blocked by the circled C if C is a noncollider on the path, and by “marrying the parents” of C and

Figure 3 Graph derived from Figure 1 after conditioning on F

its collider ancestors (as in 1 and 2 above) to show the paths opened by conditioning. Thus if we circle C in Figure 1, it will block the $E-D$ paths $E \leftarrow C \leftarrow B \rightarrow D$ and $E \leftarrow A \rightarrow C \rightarrow D$ but unblock the path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ via the new arc between A and B . If we were to circle F but not C , no open path would be blocked, but A and B would again be joined by a dashed arc as in Figure 3.

A path is closed after conditioning on a set of variables S if S contains a noncollider along the path, or if the conditioning leaves the path closed at a collider; in either case S is said to block the path. Thus conditioning on S closes an open path if and only if S intercepts path, and opens a closed path if S contains no noncolliders on the path and every collider on the path is either in S or has a descendant in S . In Figure 1 the closed path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ will remain closed after conditioning on S if S contains A or B or if S does not contain C , but will be opened if S contains only C , F , or both.

Two variables (or sets of variables) in the graph are *d-separated* (or just separated) by a set S if, after conditioning on S , there is no open path between them. Thus in Figure 1, $\{A, C\}$ separates E from B , but $\{C\}$ does not (because conditioning on C alone results in Figure 2, in which E and B are connected via the open path A). In a DAG, $\text{pa}[X]$ *d-separates* X from every variable that is not affected by X (i.e., not a descendant of X). This feature of DAGs is sometimes called the *Markov condition*, expressed by saying the parents of a variable “screen off” the variable from everything but its effects. Thus in Figure 1 $\text{pa}[E] = \{A, C\}$, which separates E from B but not from D .

Bias and Confounding

There is considerable variation in the literature in the usage of terms like “bias,” “confounding,” and related concepts, which refer to dependencies that reflect more than just the effect under study. To capture these notions in a causal graph, we say that an open path between X and Y is a *biasing path* if it is not a directed path. The association of X with Y is then *unbiased* for the effect of X on Y if the only open paths from X to Y are the directed paths. Similarly, the dependence of Y on X is *unbiased given S* if, after conditioning on S , the open paths between X and Y are exactly (only and all) the directed paths in the starting graph. In such a case we say S is *sufficient* to

block bias in the X – Y dependence, and is *minimally sufficient* if no proper subset of S is sufficient.

Informally, confounding is a source of bias arising from causes of Y that are associated with but not affected by X (see **Confounding**). Thus we say an open nondirected path from X to Y is a *confounding path* if it ends with an arrow into Y . Variables that intercept confounding paths between X and Y are *confounders*. If a confounding path is present, we say *confounding* is present and that the dependence of Y on X is *confounded*. If no confounding path is present, we say the dependence is *unconfounded*, in which case the only open paths from X to Y through a parent of Y are directed paths. Similarly, the dependence of Y on X is *unconfounded* given S if, after conditioning on S , the only open paths between X and Y through a parent of Y are directed paths.

An unconfounded dependency may still be biased owing to nondirected open paths that do not end in an arrow into Y . These paths can be created when one conditions on a descendant of both X and Y . The resulting bias is called *Berksonian bias*, after its discoverer Joseph Berkson [16]. Most epidemiologists call this type of bias as “selection bias” [16]. Nonetheless, some writers (especially in econometrics) use “selection bias” to refer to confounding, while others call any bias created by conditioning as “selection bias” [14].

Consider a set of variables S that contains no effect (descendant) of X or Y . S is *sufficient* to block confounding if the dependence of Y on X is unconfounded given S . “No confounding” thus corresponds to sufficiency of the empty set. A sufficient S is called *minimally sufficient* to block confounding if no proper subset of S is sufficient. The initial exclusion from S of descendants of X or Y in these definitions arises first, because conditioning on X descendants can easily block directed (causal) paths that are part of the effect of interest, and second, because conditioning on X or Y descendants can unblock paths that are not part of the X – Y effect, and thus create new bias.

A *back-door path* from X to Y is a path that begins with a parent of X (i.e., leaves X from a “back door”) and ends at Y . A set S then satisfies the *back-door criterion* with respect to X and Y if S contains no descendant of X and there are no open back-door paths from X to Y after conditioning on S . In a DAG, the following simplifications occur.

1. All biasing paths are back-door paths.
2. The dependence of Y on X is unbiased whenever there are no open back-door paths from X to Y .
3. If X is exogenous, the dependence of any Y on X is unbiased.
4. All confounders are ancestors of either X or of Y .
5. A back-door path is open if and only if it contains a common ancestor of X and Y .
6. If S satisfies the back-door criterion, then S is sufficient to block X – Y confounding.

These conditions do not extend to non-DAGs like Figure 2. Also, although $\text{pa}[X]$ always satisfies the back-door criterion and hence is sufficient in a DAG, it may be far from minimal sufficient. For example, there is no confounding and hence no need for conditioning whenever X separates $\text{pa}[X]$ from Y (i.e., whenever the only open paths from $\text{pa}[X]$ to Y are through X).

As a final caution, we note that the biases dealt with by the above concepts are only confounding and selection biases. Biases due to measurement error and model-form misspecification require further structure to describe them.

Statistical Interpretations and Applications

A joint probability distribution for the variables in a graph is *compatible* with the graph if two sets of variables are independent given S whenever S separates them. For such distributions, two sets of variables will be statistically unassociated if there is no open path between them. Many special results follow for distributions compatible with a DAG. For example, if in a DAG, X is not an ancestor of any variable in a set T , then T and X will be independent given $\text{pa}[X]$. A distribution compatible with a DAG can thus be reduced to a product of factors $\text{Pr}(x|\text{pa}[X])$, with one factor for each variable X in the DAG; this is sometimes called the *Markov factorization* for the DAG. When X is a treatment, this condition implies that the probability of treatment is fully determined by the parents of X , $\text{pa}[X]$.

Suppose now we are interested in the effect of X on Y in a DAG, and we assume a probability model compatible with the DAG. Then, given a sufficient set S , the only source of association between X and Y within strata of S will be the directed paths from X to Y . Hence, the *net effect* of $X = x_1$ versus $X = x_0$ on Y when $S = s$ is defined as $\text{Pr}(y|x_1, s) - \text{Pr}(y|x_0, s)$,

the difference in risks of $Y = y$ at $X = x_1$ and $X = x_0$. Alternatively, one may use another effect measure such as the risk ratio $\Pr(y|x_1, s)/\Pr(y|x_0, s)$. A *standardized effect* is a difference or ratio of weighted averages of these stratum-specific $\Pr(y|x, s)$ over S , using a common weighting distribution. The latter definition can be generalized to include intermediate variables in S by allowing the weighting distribution to causally depend on X . Furthermore, given a set Z of intermediates along all directed paths from X to Y with $X-Z$ and $Z-Y$ unbiased, one can produce formulas for the $X-Y$ effect as a function of the $X-Z$ and $Z-Y$ effects (“front-door adjustment” [2, 4]).

The above form of standardized effect is identical to the forms derived under other types of causal models, such as potential outcome models. When S is sufficient, some authors go so far as to identify the $\Pr(y|x, s)$ with the distribution of potential outcomes given S . There have been objections to this identification on the grounds that not all variables in the graph can be manipulated, and that potential-outcome models do not apply to nonmanipulable variables. However, the objection loses force when X is an intervention variable. In that case, sufficiency of a set S implies that the potential-outcome distribution equals $\sum_s \Pr(y|x, s)\Pr(s)$, the risk of $Y = y$ given $X = x$ standardized to the S distribution.

Identification of Effects and Biases

In order to check the sufficiency and identify minimally sufficient sets of variables given a graph of the causal structure, one needs to see only whether the open paths from X to Y after conditioning are exactly the directed paths from X to Y in the starting graph. Mental effort may then be shifted to evaluating the reasonableness of the causal independencies encoded by the graph, some of which are reflected in conditional independence relations. This property of graphical analysis facilitates the articulation of necessary background knowledge for estimating effects, and eases teaching of algebraically difficult identification conditions.

As an example, spurious sample associations may arise if each variable affects selection into the study, even if those selection effects are independent. This phenomenon is a special case of the collider-stratification effect illustrated earlier. Its presence is easily seen by starting with a DAG that includes a

selection indicator $F = 1$ for those selected, or z otherwise, as well as the study variables, and then noting that we are always forced to examine associations within the $F = 1$ stratum (i.e., by definition, our observations stratify on selection). Thus, if selection (F) is affected by multiple causal pathways, we should expect selection to create or alter associations among the variables.

Figure 4 displays a situation common in randomized trials, in which the net effect of E on D is unconfounded, despite the presence of an unmeasured cause U of D . Unfortunately, a common practice in health and social sciences is to stratify on (or otherwise adjust for) an intermediate variable F between a cause E and effect D , and then claim that the estimated (F -residual) association represents that portion of the effect of E on D not mediated through F . In Figure 4 this would be a claim that, upon stratifying on F , the $E-D$ association represents the direct effect of E on D . Figure 5, however, shows the graph conditional on F , in which we see that there is now an open path from E to D through U , and hence the residual $E-D$ association is confounded for the direct effect of E on D .

The $E-D$ confounding by U in Figure 5 can be seen as arising from the confounding of the $F-D$ association by U in Figure 4. In a similar fashion, conditioning on C in Figure 1 opens the confounding path through A and B in Figure 2; this path can be seen as arising from the confounding of the $C-E$

Figure 4 Graph with randomized E and confounded intermediate F

Figure 5 Graph derived from Figure 4 after conditioning on F

association by A and the $C-D$ association by B in Figure 1. In both examples, further stratification on either A or B blocks the created path and thus removes the new confounding.

Bias from conditioning on a collider or its descendant has been called *collider bias* [12, 15]. Starting from a DAG, there are two distinct forms of this bias: confounding induced in the conditional graph (Figures 2, 3, and 5), and Berksonian bias from conditioning on an effect of X and Y . Both biases can in principle be removed by further conditioning on variables along the biasing paths from X to Y in the conditional graph. Nonetheless, the starting DAG will always display ancestors of X or Y that, if known, could be used to remove confounding; in contrast, no variable need appear or even exist that could be used to remove Berksonian bias.

Figure 4 also provides a schematic for estimating the $F-D$ effect, as in randomized trials in which E represents assignment to or encouragement toward treatment F . One can put bounds on confounding of the $F-D$ association, and with additional assumptions remove it entirely through formulas that treat E as an *instrumental variable* (a variable associated with F such that every open path to D includes an arrow pointing into F) [4, 7, 15].

Questions of Discovery

While deriving statistical implications of graphical models is uncontroversial, algorithms that claim to discover causal (graphical) structures from observational data have been subject to strong criticism [17, 18]. A key assumption in certain “discovery” algorithms is a converse of compatibility called *faithfulness* [5]. A compatible distribution is *faithful* to the graph (or *stable*) if for all X, Y , and S , X and Y are independent given S only when S separates X and Y (i.e., the distribution entails no independencies other than those implied by graphical separation). Faithfulness implies that minimal sufficient sets in the graph will also be minimal for consistent estimation of effects. Nonetheless, there are real examples of near cancellation (e.g., when confounding obscures a real effect), which make faithfulness questionable as a routine assumption. Fortunately, faithfulness is not needed for the uses of the graphical models discussed here.

Whether or not one assumes faithfulness, the generality of graphical models is purchased with limitations on their informativeness. Causal diagrams

show whether the effects can be estimated from the given information, and can be extended to indicate effect direction when that is monotone [19]. Nonetheless, the nonparametric nature of the graphs implies that parametric concepts like effect-measure modification (heterogeneity of arbitrary effect measures) cannot be displayed by the basic graphical theory. Similarly, the graphs may imply that several distinct conditionings are minimal sufficient (e.g., both $\{A, C\}$ and $\{B, C\}$ are sufficient for the ED effect in Figure 1), but offer no further guidance on which to use. Open paths may suggest the presence of an association, but that association may be negligible even if nonzero. For example, bounds on the size of direct effects imply more severe bounds on the size of effects mediated in multiple steps (indirect effects), with the bounds becoming more severe with each step. As a consequence, there is often good reason to expect certain phenomena (such as the conditional $E-D$ confounding shown in Figures 2, 3, and 5) to be small in epidemiological examples. Thus, when quantitative information is used, graphical modeling becomes more a schematic adjunct than an alternative to causal modeling.

Other Reviews

Full technical details of causal diagrams and their relation to causal inference can be found in the books by Pearl [4] and Spirtes *et al.* [5]. Less technical reviews geared toward health scientists include Greenland *et al.* [6], Greenland and Brumback [9], and Glymour and Greenland [15].

Causality/Causation

While few people lack an intuitive understanding of cause and effect, a precise philosophical definition is challenging, and a practical epistemology for detecting causal relations even more so. In the practical realms of worldly sciences, methods have been established for conceptualizing, detecting, and modeling causation, some quite useful but others largely distracting.

Definition of Cause

Many attempts to define *cause* are circular, relying on synonyms (e.g., “a condition that produces an outcome”), and thus vacuous. The most widely accepted definition of cause is based on the concept of counterfactuals, and written analysis of it dates back to Hume’s [1] “An Enquiry Concerning Human Understanding”, which considers the fundamental and elusive nature of understanding causation:

“The only immediate utility of all sciences, is to teach us, how to control and regulate future events by their causes. Our thoughts and enquiries are, therefore, every moment, employed about this relation: Yet so imperfect are the ideas which we form concerning it, that it is impossible to give any just definition of cause, except what is drawn from something extraneous and foreign to it. Similar objects are always conjoined with similar. Of this we have experience. Suitably to this experience, therefore, we may define a cause to be an object, followed by another, and where all the objects, similar to the first, are followed by objects similar to the second. Or in other words, where, if the first object had not been, the second never had existed.”

Expanding on the final quoted sentence (though setting aside the previous sentence, which others have simply ignored – see below), a cause of an effect is an event or state of the world such that the effect occurs given that the cause occurs or exists, while the effect does not occur if the cause does not occur or exist, *ceteris paribus*. This definition is generally referred to as the *counterfactual definition* because either the cause exists or it does not in the actual state of the world, and the definition depends on drawing conclusions about the status of the effect in a world where the status of the cause is contrary to actual fact.

Notice several implications of the definition: The *ceteris paribus* condition (i.e., that all other things are equal) allows an event or state of the world (hereafter, this conjunction is simplified to *agent*) to cause an effect under some circumstances and fail to do so in others; the latter include other circumstances where the effect does not occur in the presence of the potential causal agent, or where it occurs regardless of that agent. If the effect never occurs when the agent is absent, the agent is called *necessary* and if the effect always occurs whenever the agent occurs, the agent is called *sufficient*. In practical contexts, the terms *necessary* and *sufficient* are generally used conditionally rather than universally, with the implication that some intuitive list of worldly conditions is held constant. At a minimum, this takes the form of assuming that nothing varies beyond the range that we believe it can vary (e.g., when assessing causes of disease, we assume that a mysterious force will not radically alter human physiology).

In most practical science (i.e., once we depart from mathematical descriptions of symbolic logic), the definition of both the agent and the outcome become imprecise. For example, is an event the same event if it occurs 5 minutes sooner or is it slightly larger or slightly more intense? Is a year sooner, much larger or much more intense? If smoking accelerates someone’s fatal heart failure by 10 years, we would agree that it was a cause of death, but if it does so by 5 min, it seems inappropriate to attribute the death to smoking. The answers to these questions determine whether an agent is a cause, because if an outcome changes enough in the presence of an agent that it is considered a different event, then the agent caused the new version of the outcome to occur (and the old one to not occur). Clearly a large enough change constitutes a different outcome. However, if we define even the smallest changes as different outcomes, then almost everything would cause almost every event that is subsequent and proximate to it, and so the concept loses most of its practical value. Every context offers practical, generally fuzzy, definitions of “same” and “different” events that fundamentally affect the definition of cause.

To fully understand the counterfactual concept of causation, special attention should be paid to the case of *overdetermination*. If there exist in a given situation multiple agents (or sets of agents), each of which is sufficient for a particular effect given the state of the world, then nothing can be said to have

caused the effect by the counterfactual definition. The counterfactual absence of any particular agent or set would not change the outcome. (Note that this means that a sufficient agent may not always be a “sufficient cause”, though the latter terminology is commonly used without regard for the presence of other sufficient agents.) This complicates practical implications and defies intuition in some contexts, and so often each of the multiple agents is called a cause, as it would be if the others were absent in a given situation. Altering the formal definition to allow for overdetermination complicates it substantially, and so it is often just left implicit that the counterfactual thought exercise about one agent can be carried out as if coincidentally present sufficient causes were absent. The “causal pie” model, below, helps illustrate some of these concepts.

The counterfactual definition of causation is not universally accepted, most often challenged on the grounds that invoking what happens in an impossible state of the world is troublesome. Alternative definitions often focus on a consistent pattern of one event following another, as in the penultimate sentence of the above passage from Hume. However, such proposed alternative definitions are usually regarded as indistinguishable from the counterfactual definition in a practical sense (since neither the counterfactual nor the universality of a pattern can be observed, and thus both are empirically based on only a finite number of observed events that form some pattern). This is evidenced by the unacknowledged equation of the two by Hume and others who quote him. When causation is accepted as fundamentally nonobservable, then any definition must incorporate something nonobservable. Given this, practical observers sometimes treat the definition as purely a matter of intuition, and refer to the counterfactual or other conceptualizations as models (i.e., simplifications that allow for extraction of information about the underlying construct), and not the definition *per se*. Throughout this chapter, the widely accepted and heuristically useful counterfactual conceptualization will be implicitly used; nothing depends on whether it is considered the definition or a model.

Empirical Implications

To observe causation, we would like to observe both the actual and counterfactual states of the world.

Since that is not possible, we usually try to observe two groups of potential objects of causation (e.g., populations of people) that are as identical as possible with respect to their response to an agent of interest, with the agent present in one group but not the other. For identical molecules in a chemistry experiment, we comfortably assume that the populations are identical. When people are the object of causation, it is difficult to justify that assumption; even sequentially comparing the same person with and without the agent, in situations where this is possible, violates the *ceteris paribus* condition due to changes in other variables over time.

Observing different groups of people, some of whom have an “*exposure*” (i.e., the agent is present at a particular level of intensity) and some of whom do not, introduces the problem of *confounding*, which exists when the two groups differ in their frequency of the outcome, even without any effect of the agent. For example, people who choose to smoke have characteristics other than smoking that make them less healthy, on average, than those who do not; so a comparison of “nonsmoking smokers” (people who actually smoke, but observed in the counterfactual state of not having smoked) and actual nonsmokers would show a difference in health outcomes. A simple comparison of smokers to nonsmokers would, thus, imply that smoking is more unhealthy than it actually is. Statistical models that incorporate other variables to “control for” their effects may partially correct for this problem. These covariates are generally called *confounders*, though only some of them actually are, as discussed below in the discussion of causal diagrams (see **Confounding**). The emphasis on confounders, however, is the source of much confusion about the nature of causation and confounding: Confounding is often mistakenly thought of as the difference between groups (with respect to the outcome, independent of the agent) caused by the confounders, when actually it is merely the difference, without regard to its cause. The covariates are not so much confounders as they are “unconfounders” [2], variables included in a statistical model with the hope that they reduce confounding, and whatever confounding the agents measured by those variables actually *causes* requires an analysis as complicated as any other study of causation.

Another solution to the problem of confounding is to randomize a population into groups and intervene by assigning each group to have the agent or

not (e.g., a clinical trial that gives some people a drug and others a placebo – see **Randomized Controlled Trials**). This replaces systematic confounding due to unknown systematic differences that are associated with the distribution of the agent in the world, as it exists with random confounding which can be assessed statistically. The “random error” in a randomized trial is seldom recognized as confounding, but attention to the concepts of causation and confounding shows that it is confounding a random allocation will, on average, generate groups that, apart from the effect of the agent, have the same outcomes. However, the actual allocation in a particular case will likely produce groups that are not exactly this average, and thus fit the definition of confounding. Because this confounding is generated through a known random process, its distribution can be assessed and reported using familiar confidence intervals and test statistics. These statistics are often calculated and reported when there is no randomization, but there they only represent random sampling deviations from the unknown actual confounded association, not from the unconfounded association as in a randomized experiment.

Randomized experiments are often erroneously called the *gold standard* research design in health science and similar fields. This misconception appears partially due to the incorrect belief that a randomized experiment allows direct observation of causation, while nonrandomized observational studies do not. In fact, direct observation of causation remains impossible in randomized experiments; allocating an agent at random to two groups of people and contrasting their response in real-world settings is still only a proxy for knowing the response that would have occurred in a single group had their exposure status been changed and all else held equal. For this reason, the value of any study for assessing causation, regardless of design, must be judged based on how well it approximates the counterfactual contrast. Randomized experiments have the advantage that they make confounding follow a predictable statistical distribution, rather than being unknown and potentially very misleading. However, in other ways, randomized trials are an inferior approximation for the counterfactual, as compared to certain observational studies: they can have nonrandom lack of compliance with the assigned exposure or nonrandom subject loss, and the study population and version of the agent

under experimental conditions often differ from the counterfactual contrast we are actually interested in.

Categorizing Causal Response Types

Based on ideas from Miettinen [3], Greenland and Robins introduced four basic causal response types, with respect to a particular agent: “doomed”, “causative”, “preventive”, and “immune” [4]. These were defined in the context of epidemiology, but the concept easily generalizes. Individuals who are doomed will have the outcome whether the agent is present or not, and those who are immune will not have the outcome, regardless of exposure to the agent. Thus, in the given state of the world, for these two types of individuals, the agent is not a cause of the outcome. The causative types are those who have the outcome if the agent is present, but not otherwise, the standard definition of the agent as a cause. The preventive type includes those for whom the absence of the agent causes the outcome (which is the intuitive definition of an agent that prevents an outcome).

Causal response types can only be inferred or modeled, since empirical observation of an individual’s exposure and subsequent outcome status can only narrow the possible types to two, and distinguishing between them requires knowing a counterfactual. For example, if we observe that an individual was exposed to an agent and later developed the outcome, then the individual was either doomed or had a causative response, but we can only imagine what the outcome would have been had the individual not been exposed, because we cannot repeat the observation modifying the exposure while holding all else constant. Similarly, if we observe that an individual was not exposed to an agent and did not later develop the outcome, we cannot determine if the individual was immune or had a preventive response. Maldonado and Greenland tied this causal response classification to the counterfactual definition of cause and showed the role of these concepts in understanding basic epidemiologic concepts [5]. In particular, they illustrated that the aim in etiologic research should be to find two groups that are identical in terms of their responses to the agent (are “perfect substitutes”); with that achieved, the outcomes in one group are what would have been observed in the comparison group if the exposure distributions had been exchanged, and the difference is caused by the agent.

Simple Causal Relationships

Evolution favors the development of some intuitive recognition of causation in an organism with decision-making capacity, because of its obvious survival advantage. However, informal observation and formal research in cognitive psychology suggest that even in humans this intuition is quite limited. There tends to be an intuitive recognition of only the simplest causal relationships, and a creation of perceived causation where it does not exist (e.g., superstition). Formal models, including some presented below, are often needed (though not always sufficient) when intuition is misleading.

The simplest causal relationships involve a single agent that is necessary and sufficient for a particular outcome. This view is overly simplistic for the causation of most natural phenomena, and indeed, represents a case where the agent and outcome are in some sense part of the same phenomenon. It is worth mentioning primarily because this unrealistic relationship is often implicitly invoked in discussions of causation, usually introducing confusion or obscuring scientific challenges. For example, discussions of disease often ask whether *the* cause is environmental or genetic, as if one agent were necessary and sufficient and others irrelevant, even when evidence shows no known class of agents is either necessary or sufficient.

Slightly more complicated and more realistic causal relationships are those where an agent is either necessary or sufficient for producing a particular outcome, but not both. Sufficiency describes the simple causal relationships that we seldom think of as causation (e.g., if I grasp a coffee cup and raise my hand, the cup will rise), as well as worldly “laws” and physical forces (e.g., gravitational attraction). An example of a necessary agent can be found in infectious diseases, when the particular disease occurs only in the presence of the corresponding infectious agent. A careful examination shows that this (at best) borders on circularity, since even if every symptom of the given infectious disease were present, if the infectious agent could be shown to be absent we would declare that the particular infectious disease was absent, the necessity of the cause thus being created by definition. Nevertheless, if we do not push too hard on this concept, a necessary agent is a useful starting point for modeling causation, and is the basis for one of

the earlier attempts to assess causation in complicated worldly phenomena.

Henle–Koch Postulates

The Henle–Koch postulates for identifying causal agents of infectious diseases are based on a single-agent causal model [6]. These postulates, dating from 1884, are as follows:

1. The parasite occurs in every case of the disease in question. . .
2. It occurs in no other disease. . .
3. After being. . .isolated and. . .grown. . . it can produce the disease anew.

These postulates are useful for overcoming the view of causation as isomorphic (since the parasite is not necessarily sufficient for the disease). However, even for an infectious disease, the simple necessary cause model has flaws. The requirement that a parasite be specific to a single disease is sometimes misleading, particularly because a spectrum of severity of symptoms arguably represents different disease outcomes. More important from the perspective of causal modeling, when the parasite is not sufficient for disease to occur, the postulates offer no conceptualization of factors that make someone susceptible to the infection, which are also causes. Finally, chronic infections are now known to sometimes cause chronic diseases such as cancer, which can also be caused independently by other agents, and so infectious agents cause diseases for which they are not necessary.

Multifactorial Concepts of Cause

For most effects, there is no single sufficient causal agent, and a multiplicity of agents is required to form a sufficient combination. This creates substantial complications for identifying causal relations, many of which are not obvious without modeling. In theory, the complicated interaction of causes is well understood in both biological and social sciences. A 1960 textbook of epidemiologic methods presented a causal diagram called the *web of causation* to depict how multiple factors lead to disease [7]. An illustration like a web emphasizes the complexity of causal relationships that may not be obvious to many

observers. Simpler and more formalized depictions, such as those presented below, are more useful still, serving as models of the implications of causation.

Interaction of Causes and the Causal Pie Model

In 1976, Rothman presented what he later dubbed the causal pie model to illustrate that a given disease results from one or more sufficient sets of component causes and disease occurs when a person has been exposed to all components of a sufficient set [8, 9]. This model depicts each sufficient set of agents as forming a circle, with each agent depicted as a slice of pie (Figure 1). The specifics of the illustration contain no information beyond the list of component causes (e.g., the size of the pie slice does not matter), but it has been adopted as a standard presentation in epidemiology. In some presentations, one slice of the pie is labeled U, representing posited unknown cofactors that are necessary for the included known factors to be collectively sufficient, because there are relatively few causal mechanisms where the known agents are sufficient [10].

This simple depiction parsimoniously illustrates that the component causes in a sufficient set interact to produce an outcome, and thus demonstrates several important aspects of causation that are not intuitive to most observers. The simplest is that because multiple agents combine to cause a single effect, and changing the status of any one of them would eliminate the effect. This means that the presence of other agents alters whether a particular agent is a cause of an outcome in a particular instance. An agent actually causes a particular outcome that it has the potential to cause only if the *causal complement* (that is, all the other elements in a pie) for at least one pie is present. The observable degree of interaction between any two component causes depends on how many sufficient sets contain both of those agents and how often the other elements in those sets are all present.

Figure 1 Causal pie diagrams

Conceptualizing sets of causal complements also allows prediction of *effect modification*, wherein an agent is expected to have different effects depending on the presence of other known variables (e.g., if we think that some of the causal complements for the agent, as eating meat as a cause of colon cancer includes being older, then we should expect the agent to cause the outcome in a smaller portion of younger people compared to older people). With this insight, it is possible to stratify a model based on an effect modifier or otherwise predict and account for the different effects of the same agent between or within studies.

Causal pies can be used to illustrate the concept of *attributable fraction*, the portion of all outcomes in a population that are caused by a particular agent (which can be determined by counting up the individuals for which (a) one or more causal pies are filled when the agent is present, but (b) no pies are filled if the agent is absent). This also illustrates that while the fraction of events attributable to a single-component cause cannot exceed 100%, there is no bound to the sum of these fractions across all causes (that is, it is to be expected that we will discover causes of a disease such that the proportion of cases of disease attributed to a cause, summed across all causes, is far more than 100% because multiple causes are usually identified for each case).

An additional lesson from the causal pie model is that the quantified measure of the agent–outcome association may be large or small and still represent causation. Quantitative estimates of causal relationships depend on how often causal complements are present (and thus how often an agent that is potentially a cause actually is a cause), as well as the prevalence of sufficient causal sets that do not include the agent in question. In concrete terms, the probability that an individual’s smoking will cause him to get oral cancer changes with the presence of complementary agents; there is a causal pie that includes smoking (plus unknown factors) and another that includes smoking and heavy drinking (plus unknown factors), and thus whether smoking is causal sometimes depends on whether the individual drinks heavily. However, the risk ratio for the population (i.e., the multiplicative increase in the probability of the outcome) also depends on the rate of oral cancer that exists when smoking is absent, since a higher baseline rate in the absence of the agent lowers the relative risk. So in the West, where oral cancer is quite rare

in nonsmokers, smoking increases the baseline risk by a factor of about 10, but elsewhere in the world, where the baseline incidence is as much as 10 times higher, the same absolute risk from smoking may only represent a twofold relative risk. However, both of these relative risks represent causation, and may even represent the same number of cases caused by smoking in a population of a given size.

As noted above, whether changing the timing of an event makes it a different event is a matter of subjective definition. Another element of timing that can be recognized using the causal pie model is the induction period, the time between a component cause becoming present and the outcome event. This period depends on how long it takes to complete the sufficient set. For example, for disease that results from the combination of chronic infection and a period of immunosuppression, the infection may be present for a period until a bout of immunosuppression occurs, that period being the induction period; the induction period for the immunosuppression, in that case, is zero (because it is assumed that the two agents form a sufficient set and the other agent is already present). This sequence should not be confused with a series of events such that X causes Y and then Y causes Z, which cannot be effectively illustrated in a model like the pie that is only an unordered list.

Probability and Causation

Conceptualizing causation in an empirical scientific context requires the use of probability. Because we cannot generally observe all determinants of particular events such that we can predict their future occurrence with certainty, there is generally some degree of uncertainty regarding the outcome of known or suspected causal agents. In the context of the causal pie, if the status of a causal complement for an agent is only known probabilistically, then whether an agent is a cause or not can only be known probabilistically. If an agent is absent and we consider the counterfactual state of it being present, only the probability of the outcome that would result can be known. Thus, in a population, the expected value of the frequency of the outcome (and its statistical variance) under the counterfactual presence of the agent can be assessed.

Empirically, the reasoning flows in the opposite direction: The frequency or proportion of individuals with an outcome is observed in two groups with

different status for the agent, and the probability that the agent causes the outcome for an average individual is inferred to be the estimated proportion of the group for which it is causal. Often, this measure of effect is expressed in terms of the increase in the probability of the outcome caused by the agent. Since the outcome either occurs or does not, for a given individual, the estimated increase in the probability of an outcome is the average effect at the population level, when the causative types are added to the doomed types. Each individual with the outcome is still either causative or doomed, and we cannot know which, but we can estimate the probability based on the relative sizes of those groups. Recognizing this can eliminate some confusion that results from simplistic concepts of causation among people who are not experts in scientific reasoning. For example, physicians often declare that a particular patient's cancer was caused by a particular exposure, presumably because they have learned that the exposure increases the probability of getting that cancer; what they fail to understand is that the patient in question might have been doomed with respect to that agent.

Note that inherent in this discussion is a conceptualization of probability as subjective, empirically estimated based on frequency, but stemming from observer ignorance. Under this conceptualization, for each individual an agent is either causal or not, so probabilities of causation between zero and one exists only in the assessment of an observer who does not know the individual's true type. Causation as a deterministic process, as portrayed in the causal pie model or the conceptualization of causal response types, can translate into empirical models that incorporate probability by equating the probability that an agent causes an outcome in a given instance with the probability that the causal complement is present.

Causal Pathway Diagrams

Diagrams of hypothesized causal pathways typically use arrows connecting boxes or words to illustrate assumed relations between causal factors and specific outcomes. Such diagrams contain information that is absent in models that just list component causes, like causal pies. Causal pathway models show the sequence and direction of hypothesized relations among variables and are particularly useful

for distinguishing between causation and noncausal association, as well as how proximal a cause is (whether it causes the outcome by affecting other posited causal agents, or without such intermediates), and for identifying variables that should be measured and controlled to obtain unconfounded estimates. However, such diagrams usually lack information that a pie model provides about interactions of causes and about why a measure of association might be large or small.

Causal pathway diagrams include formal, mathematically analyzable diagrams as well as informal illustrations, such as webs of causation. Figure 2 portrays hypothesized relations between an exposure, an outcome, and other variables. This type of diagram demonstrates whether other factors are confounders, intervening factors, or exist on a separate pathway from the agent in question (in the latter case, the diagrams usually provide no way to distinguish elements of the causal complement from independent sufficient causes). The example contains clear information about the hypothesized causal pathway, though as drawn it does not show whether a relationship is positive/causal or negative/protective (plus and minus signs are sometimes added to an arrow to indicate this), or strong or weak. Agent “exposure” is a cause of the outcome in the figure because it causes a change in agent “intervening factor”, which in turn causes a change in “health outcome”. If we acted to hold “intervening factor” constant, regardless of the status of “exposure”, then “exposure” would cease to be a cause of the outcome. “Confounder” is a cause of the outcome, and still would be if we held the “intervening factor” constant because it would no longer be a cause *via* “exposure”, but it would still be a cause *via* the direct pathway.

The most useful mathematical causal modeling using arrow-and-box models is based on directed acyclic graphs (DAGs), which impose intuitive rules that allow more precise mathematical analysis. In particular, the lines connecting entries are single-headed arrows (in the case of causal diagrams, this

Figure 2 A casual pathway diagram

means they are all hypothesized causal relationships) and the arrows form no circular paths. These rules are intuitive, given the standard conceptualization of causation in which cause must precede effect in time, and time flows monotonically. (Quasi-circularities, such as positive feedback loops, can be portrayed in DAGs by incorporating time into the causes and effects in the graph; e.g., a weakened immune system at time 1 causes disease at time 2, which causes a weakened immune system at time 3.) The mathematics for using DAGs to determine which variables must be controlled to obtain unconfounded effect estimates (and which must *not* be controlled) produces relatively easy-to-apply rules [11, 12]. DAGs allow the identification of confounders, some of which fit the intuitive definition of a factor that causes confounding (e.g., the confounder in Figure 2, which causes both the exposure and the outcome, thereby causing the population with the exposure to have an increased outcome frequency for reasons other than the effect of the exposure), and some of which do not, but should be controlled statistically because the actual causal confounders are not known or perfectly measured. Thus, the graphs can serve as aids for constructing quantitative models for the estimation of causal effects [13].

Such models have the potential to substantially improve the epistemology of epidemiology and other observational social sciences, though they are generally overlooked despite their obvious usefulness. For example, researchers often conduct statistical analyses by constructing regression models that include every measured variable that might be related to the agent or effect of interest (perhaps dropping those that fail to meet a statistical significance test that actually tells us nothing about whether they actually reduce confounding). Having included in the regression model all available variables from the dataset, researchers often claim that they have controlled for confounding and readers naively believe that confounding is eliminated. However, thinking through the construction of a causal pathway diagram, incorporating background knowledge, often reveals additional hypothesized confounders that were not included in the model. Analyzing hypothesized patterns of causation using a DAG often reveals that adjusting for some of the variables included in the model, such as intervening factors, will make the effect estimate less accurate rather than more so,

something that statistical tests of associations within a dataset cannot reveal [14].

Embellishments of causal pathway diagrams beyond DAGs provide further insights. Predicting the effect of an agent through a complicated pathway can be accomplished by adding indicators of the strength of posited causal relationships along the path. Effects of an agent through multiple pathways can be illustrated to show whether different pathways reinforce the same effect or counteract one another. The different manifestations of effect modifiers and confounders in the diagrams also illustrate how these types of variables are quite different, even though they are often confused when all potential agents are merely thought of as other variables in a dataset.

In general, explicitly modeling causal pathways, based on existing knowledge about the phenomenon being studied that is outside the data being analyzed, and then designing statistical models based on hypothesized pathways [13], rather than on naive statistical significance tests or variable selection algorithms, can improve qualitative assessments of whether an agent is causal and quantitative estimates of its effect.

Inferring Causation from Observed Association

Ultimately, no matter how we define, logically analyze, and model causation, scientific analysis is concerned with inferring it about the physical world, in the context of general agreement that we cannot directly observe it. Strictly speaking, under the counterfactual definition (and under alternative inductive definitions), we can never know if an inference of causation is correct (especially in a particular case), and thus never know for sure whether the inference is right. However, at a practical level, modern science is built on the notion of “theories”, which are rules about how the world works that generally include causal relationships corresponding to hypotheses that have stood the test of time, having been supported consistently by empirical evidence and fitting with other widely accepted theories. The terminology of causal inference implicitly recognizes that such worldly conclusions can never take the form of proof or laws, as exist in axiomatic systems.

Worldly causal inference can be based on hypothesizing a causal relationship, usually motivated

by observations, and then assessing whether its implications are empirically borne out. This is typically coupled with trying to rule out explanations for the observation that do involve the hypothesized causal relationship. (Perhaps a more common practice is merely observing an empirical association in a dataset and declaring it to be causal, but this is an example of the naive simplistic views of causation mentioned above.) Although attempts to systematize the empirical process for inferring causation have been proposed, defining a method for inferring causation is quite similar to defining “the” scientific method, a construct that modern philosophy of science generally dismisses as nonexistent. Just as the scientific method is often accepted to be, roughly, as whatever it is that good scientists have found to be useful to achieve their goals, good practice seems to better define proper causal inference than does any attempt to provide a recipe for it.

However, though there is no accepted recipe, there are widely accepted ingredients, which are based on hypothetico-deductive reasoning [15], methods for ruling out alternative explanations for an observed association, and other analysis, including

- replication of results to show that an association is systematic rather than an accident of one dataset (this should include observation of the association under different circumstances where the hypothesized causal relationship should still hold);
- observation of changes in the association across populations with different distributions of hypothesized effect modifiers;
- observation that the association is absent for populations that lack the hypothesized causal complements;
- observation that the association disappears when a hypothesized intervening factor in the causal pathway is held fixed, and similar observations of predicted effects of changing other variables;
- observation of the predicted effects of controlling for confounders and other covariates of the agent and outcome, possibly including randomized trials;
- analysis of confounding and measurement errors, based on studying hypothesized sufficient sets or causal pathways that do not include the agent in question, to rule them out as explanations for apparent effects of the agent; and,

- perhaps most important, assessment of how well the populations that are being compared, with and without the agent, approximate the true counterfactual contrast.

This list reflects how implications of a given hypothesis are sometimes not completely obvious, and thus the above models and formalizations are often quite useful for directing scientific inquiry. The empirical predictions of a hypothesis are not clear without envisioning causal pathways, and the causal implications of previous observations are similarly obscure.

One class of tools that are sometimes presented as being useful for inferring causation, but which are not supported by either axiomatic logic or empirical evidence of usefulness, are commonly called *causal criteria* [16]. These are lists of considerations, such as strength of association, consistency across studies, and scientific plausibility or coherence, that supposedly help distinguish between causal and noncausal associations [17]. These tools are popular in health sciences, though not in similar social sciences [18]. Such lists consist primarily of commonsense considerations that should be part of the *ad hoc* process of scientific thinking that is sketched above. As such, they are potentially useful, given the ironic rarity of common sense.

It is generally accepted that no set of criteria could provide indisputable evidence of causation; it is easy to construct examples that show that any proposed condition can be met in the absence of causation [10]. Furthermore, as has been pointed out elsewhere [18, 19], these lists do not actually constitute criteria (i.e., there is no metric for determining if a particular condition has been met), let alone provide a demonstrated method for drawing more accurate conclusions. Though the commonsense advice seems likely to improve rather than hurt inference, there is no systematic evidence that inferences informed by such lists are more likely to stand the test of time or otherwise prove to be better than those that are not. When causal “criteria” are invoked by authors for the assessment of evidence, it is done inconsistently [20], and it appears authors often “deploy” [21] causal criteria to rhetorically bolster their conclusions about the presence or absence of causation, rather than employ them to aid inference.

The individual whose name is most closely associated with causal criteria is Austin Bradford Hill

for his list of causal considerations [22], often called the *Bradford Hill Criteria*, despite Hill’s own statement that there are no “‘hard-and-fast rules of evidence’ for causation” [p. 299]. Hill clearly described his list as “considerations”, not criteria, and expressed caveats about their limits. Hill’s address that presented his considerations actually contains a useful mix of epistemic approaches to inferring causation, and using that information to inform decisions, when muddling through a complicated and highly incomplete science [18]. He alluded to most of the “ingredients” that appear in the above list of methods for inferring causation, some of which are captured in lists of “criteria” and some of which are not, but did not imply that he (or anyone else) could offer a complete recipe for inferring causation in complex social sciences.

It is worth noting that because inferred causation cannot be definitive, all decisions that are based on such inference are based on uncertainty, though they still must be made. Hill [22, p. 300] noted that conclusions of causation are often quite uncertain but this “does not confer upon us a freedom to ignore the knowledge that we already have, or to postpone the action it appears to demand at a given time”. Optimal practical application of causal conclusions requires assessments of how certain the conclusion is, along with assessment of the costs and benefits of actions given the accuracy of the conclusion (using methods from economics known as *policy analysis*); efforts to infer causation while ignoring policy analysis are of little value to the goal, in Hume’s words, of regulating future events by their causes. Careful consideration of what causation is and the limits of how well we can know it provides tools for formal analysis and suggests methods for inference, but also immunity to the paralysis that can be caused by the pursuit of certainty.

Censoring

Censoring is commonly used to denote a type of sampling scheme or to describe a type of incomplete data. By censored data, we mean that a random variable of interest is only partly known, instead of being observed exactly. In many applications of risk assessment, the random variable is the time to some event such as the occurrence of infection, tumor, or a particular risk event under study. A typical example of censored data occurs in tumorigenicity experiments in which occurrence or prevalence rates of some tumors are of interest [1–3]. In this situation, the occurrence of tumor in study animals often cannot be directly observed while they are still alive, and the only way to detect these tumors is to euthanize (sacrifice) the animals or wait for their natural death. As a consequence, we know only whether a tumor is present or absent at the time of death or sacrifice, we do not know the exact time that the tumor arose. Censoring is also common in medical studies in which the response variable is time to a certain event or failure time [4].

It is worth noting that another type of sampling scheme or incomplete data that is related to censoring is truncation, which is described in a different article (see **Truncation**) and means that a random variable is observed only if it is within a certain window. To give an idea of the two types of incomplete data and to compare them, consider a simple example: let T be the age of an animal at which a lung tumor occurs. Suppose that the animal is under the study from birth and the study stops at the age C (e.g., $C = 2$) of the animal at which the animal is still lung tumor free. Then the only information available about T is $T \geq C$ and we say that T is right censored. That is, we have censoring. On the other hand, suppose that the study starts when the animal is at age U (e.g., $U = 1.5$) and the study includes only those subjects that are lung tumor free at the beginning of the study. Then the animal is included in the study only if $T \geq U$ and we say that T is truncated at U . That is, we have truncation. Note that with truncation, the variable T could be exactly observed (e.g., $T = 2.5$), while in the presence of censoring, the exact value of T (e.g., $T = 2.5$) is not known. It is apparent that censoring and truncation can occur individually or together.

In general, there are several types of censoring, including right censoring, left censoring, interval censoring, and double censoring. In the following sections, we describe each of these in detail and briefly discuss commonly used inference models and procedures.

Right Censoring

Right censoring is perhaps the most common censoring in practice and the one that has been studied the most in the literature [4]. Consider a study of some response variables that represent times to certain events. By right-censored data, we usually mean that the variable is either observed exactly or known only to be greater than another variable, commonly referred to as the *censoring variable*. This can occur, for example, when study subjects drop out of the study for reasons unrelated to the variable under study or when the study has to stop. In this situation, if the event under study has not occurred yet, then the only information available about the variable is that it is greater than the time at which the subject dropped out or the study was stopped. Right-censored data arising from n independent subjects are commonly represented in the form $\{x_i = \min(T_i, C_i), \delta_i = I(X_i = T_i)\}_1^n$, where the T_i 's denote the response variables of interest, and the C_i 's the censoring variables. Thus, the likelihood function can be written as

$$L = \prod_{i=1}^n [f(x_i)]^{\delta_i} [1 - F(x_i)]^{1-\delta_i} \quad (1)$$

assuming that T_i and C_i are independent, where f and F denote the pdf (probability density function) and cdf (cumulative density function) of the T_i 's, respectively.

There exists a great deal of literature on statistical analysis of right-censored data; some excellent books on this topic include Cox and Oakes [2], Kalbfleisch and Prentice [1], Klein and Moeschberger [4], and Lawless [5]. For inference about right-censored data, typically, three types of problems have been extensively investigated: nonparametric estimation of a distribution or survival function, nonparametric comparison of several distributions or survival functions, and regression analysis. For the nonparametric estimation, the most famous procedure is the Kaplan–Meier estimate initially proposed in Kaplan and Meier [6]. It has a closed form expression, and its properties have been well studied.

For nonparametric comparison of survival functions, a number of procedures have been developed, and the most commonly used one is perhaps the log-rank test [4]. The log-rank test statistic is the summation of the observed numbers of the events minus the expected numbers of the events. In terms of regression analysis of right-censored data, the first model that one learns is the proportional hazards or Cox model proposed in Cox [7]. It specifies that the hazard function of T_i at time t , the conditional density function of T_i given that T_i is greater than or equal to t , has the form $\lambda(t|Z_i) = \lambda_0(t) \exp(Z_i'\beta)$, where $\lambda_0(t)$ denotes the baseline hazard function, Z_i is the covariate vector associated with subject i , and β denote regression parameters. For inference about this model, Cox [8] proposed a partial-likelihood approach that has been proved to be very effective and useful, and generalized to many complex situations [4].

Left Censoring

Left censoring can be seen as the opposite of right censoring in terms of the structure. A left-censored observation usually means that the time to the event of interest is known only to be smaller than a specified value [6]. A common reason for left censoring is that the event of interest has occurred before the study began or before the subject entered the study. Another common reason is the inability to measure the variable of interest when it is below a certain level, for example, when the value is below than the sensitivity of the measuring device. An adverse event related to a drug sometimes can be determined only when the severity of the event exceeds a certain degree. Little research has specifically addressed the left censoring because it does not occur as often as right censoring, and it can be treated similar to right censoring or as a special case of interval censoring.

Interval Censoring

Interval censoring is a censoring mechanism that is more general than either the left- or the right-censoring mechanisms, and it has been attracting more and more attention [9]. Interval-censored data usually refer to the incomplete data in which the time to the event of interest is observed or known only to fall within an interval or some window of time. In

other words, one knows only the range within which the event occurred, but not the exact occurrence time. A typical example of interval-censored data is given in a follow-up study in which each study subject is observed or monitored periodically, and their observation times may differ from subject to subject. In this case, the variable of interest is known only to have some value within the interval given by the last observation time at which the event had not yet occurred and the first observation time at which the event has occurred. If the interval contains either a single point or infinity, then the interval-censored data reduce to right-censored data. On the other hand, if the interval contains either a single point or zero, the data reduce to left-censored data.

Another important special case of interval-censored data is the so-called current status data [10]. In this situation, each subject is observed only once to obtain the status of the occurrence of the event of interest at the observation time. In other words, the observation of the time to the event is either left or right censored. Many tumorigenicity experiments produce this type of data for the tumor onset time [11]. Cross-sectional data provide another example of current status data [12]. Note that for the first case, current status data result from the inability to measure the variable directly and exactly, and for the second case, they are observed because of the study design. Current status data are sometimes referred to as *case I interval-censored data*, and the general case is referred to as *case II interval-censored data* [9].

As before, let T denote the response variable of interest or the time to the event of interest, and let $F = \Pr(T \leq t|X)$ be its cdf, given a vector of covariates X . Suppose that observed data can be represented by $\{I_i, X_i\}_{i=1}^n$, where $I_i = (L_i, R_i]$ is the interval known to contain the unobserved time associated with the i th subject, and X_i are the covariates associated with subject i . Let $\{s_j\}_{j=0}^{m+1}$ denote the unique ordered elements of $\{0, \{L_i\}_{i=1}^n, \{R_i\}_{i=1}^n, \infty\}$, and α_{ij} be the indicator of the event $(s_{j-1}, s_j] \subseteq I_i$. Then the full-likelihood function is proportional to

$$\begin{aligned} L &= \prod_{i=1}^n \{F(R_i|X_i) - F(L_i|X_i)\} \\ &= \prod_{i=1}^n \left[\sum_{j=1}^{m+1} \alpha_{ij} \{F(s_j|X_i) - F(s_{j-1}|X_i)\} \right] \quad (2) \end{aligned}$$

assuming that the mechanism generating I_i is independent of the response variable.

For the one-sample problem associated with interval-censored data, a few algorithms have been developed to obtain the nonparametric maximum-likelihood estimate of a distribution function. The simplest one is the self-consistency algorithm proposed by Turnbull [11], which can be seen as an application of the EM (expectation-maximization) algorithm. This approach is easy to implement, but is known to have a slow convergence rate. The one-step EM algorithm proposed by Rai and Matthews [13] is not only self-consistent and faster, but also avoids boundary problems. Some alternatives that converge faster than the self-consistency algorithm include the convex minorant algorithm introduced in Groeneboom and Wellner [12] and a hybrid algorithm developed by Wellner and Zhan [14]. All the above algorithms are iterative and, in fact, there is no closed form for the estimate.

For regression analysis of interval-censored data, a number of methods have been developed independently or as generalizations of the approaches for right-censored data. Among regression models used to describe interval-censored data, as with right-censored data, the proportional hazards model is perhaps the one most commonly used [14]. Other models that have been investigated include the accelerated regression model [15], the additive hazards model [16], the proportional odds model [17], the logistic model [18] (see **Logistic Regression**), and the linear transformation model [19]. See Sun [8] for inference about these models and statistical approaches for other related problems such as nonparametric comparison of treatments based on interval-censored data.

Double Censoring

To this point, we have defined the response variable as the duration from time zero to an event. A more general situation that occurs in practice is that the response variable represents the time between two related events. Thus, double censoring occurs when the observations of the occurrences of both events suffer censoring discussed above [20]. In this case, the analysis is more complicated because the likelihood function involves not only the distribution of the response variable of interest but also the distribution of the originating event that defines the response variable. Following De Gruttola and Lagakos [21], who

first investigated this type of censoring and proposed a self-consistency algorithm for estimation of the distribution function, many authors have considered the inference about doubly censored data. See Sun [22] for a review of the related literature.

Other Censorings

The discussion so far has focused on univariate censoring or censoring of one response variable. Sometimes, a study may involve several response variables and all of them suffer censoring, either of the same type or of different types [22]. Also, in the above discussion, it was assumed that censoring is independent of the random mechanism generating the response variable of interest. In some situations, this may not be true, i.e., the censoring variable and the response variable may be related [23]. Another type of censoring that was not discussed above occurs when a response variable of interest is observed exactly if it belongs to an interval and is left or right censored if it is to the left or right of the interval. This type of censoring is also sometimes referred to as *double censoring* in the literature [23].

Change Point Analysis

Change point analysis refers to the statistical method of characterizing changes in the underlying nature of a response variable over a specified range of values of a predictor variable. As an example, one of the most oft-cited change point examples from the literature consists of a historical data set containing the length of time intervals (in days) between coal mining disasters with more than 10 men killed during the period 1851–1962 in Great Britain. The data set was first introduced by Maguire *et al.* [1] and subsequently corrected and updated by Jarrett [2]. A plot of the length in days for each successive interval is shown in Figure 1.

For this example, the response variable is the length of the intervals between accidents and the predictor variable is time. One might ask if there is evidence that the average interval length has changed significantly over time. Considering Figure 1, there appears to be periods between the 50th and 60th intervals, the 70th and 80th intervals, and the 100th and 109th intervals where the average time between such accidents greatly increases. Over these time periods, the occurrence of annual *risk* of an accident appears to decrease significantly. A change point analysis, for this example, might consist of estimating the exact times such changes in the mean level occurred as well as developing estimates for the mean level before and after each estimated change point. Of course, the end goal of the analysis might be to

Figure 1 A plot of the interval length in days between successive coal mining disasters

relate the estimated times where the changes occurred to real-world events. Examples of statistical methods used to perform a change point analysis for this coal mining data may be found in West and Ogden [3] and Raftery and Akman [4]. Since the coal mining data is collected over time, there is also a suite of statistical methods in the area of *intervention analysis* designed to model this type of changing behavior.

The above example illustrates potential abrupt changes in the mean interval length over time. These abrupt changes in the response are frequently referred to as *discontinuous* change points. This implies that some underlying functional governing the response is a discontinuous function of the predictor variable. The simplest mathematical model with a single discontinuous change point in the mean level is given by

$$E(Y(x)) = \begin{cases} \mu & \text{for } x < \theta \\ \mu + \beta & \text{for } x \geq \theta \end{cases} \quad (1)$$

where the response variable $Y(x)$ has an expected value of μ for values of the predictor variable, x , less than the change point θ and a mean level $\mu + \beta$ for values of x greater than or equal to θ . In this case, β represents the *size* of the discontinuity at the change point. The values μ , β , and θ must be estimated to fully specify the model. In addition to point estimates for these quantities, confidence intervals that reflect the uncertainty in the estimates should also be computed. If a confidence interval for β contains the value zero, then the entire change point model may be statistically insignificant, meaning that there is no strong evidence of a change in the mean response. A model such as the one above might be appropriate when there is an introduction of a new factor influencing the response variable, which has an immediate sustained impact on the response. In the context of the coal mining data, such a factor might be the implementation of new safety procedures by the coal mining industry.

In many settings, the above model may not be appropriate as abrupt changes in the response are not expected. This is most often the case in biological settings where, for example, an organism may be expected to withstand exposure to a certain amount of exposure to a toxic substance before it begins to gradually deteriorate. Perhaps the simplest mathematical model for this type of behavior is called

the *onset-of-trend model*, which is given by

$$E(Y(x)) = \begin{cases} \mu & \text{for } x < \theta \\ \mu + \beta(x - \theta) & \text{for } x \geq \theta \end{cases} \quad (2)$$

where the expected value of the response $Y(x)$ is constant at μ for x less than θ but then either increases or decreases from this value depending on the sign of β as x increases beyond θ . The continuous nature of the above mean response allows for a gradual change in the mean rather than an abrupt change. West and Kodell [5] fit the onset-of-trend model to data on the body weight gain (or loss) in grams for Fischer 344 rats treated with aconiazide over a 14-day period in dose groups of 0, 100, 200, 500, and 750 mg kg⁻¹ body weight. Figure 2 shows the raw data for this example along with the fitted change point model where the estimated change in mean weight gain is estimated to occur at a dose of approximately 350 mg kg⁻¹ body weight. The 95% lower confidence limit on the change point was computed to be 242.69 mg kg⁻¹ body weight. If this lower limit had been below zero (the lower limit of the observed dose predictor), the change point model might be statistically insignificant.

The above models are examples of models for changes in mean response over the predictor variable. Change point analysis can be conducted for other

Figure 2 The onset-of-trend model for the aconiazide data

underlying characteristics of the response variable as well. For example, Hsu [6] and Inclan and Tiao [7] develop statistical methods to identify shifts in the variance of a response variable rather than for the mean response. In addition to models for other response characteristics, one may also develop much more complicated functional models relating the response characteristic to the predictor variable. This underlying functional relationship may be estimated by either specifying a complicated parametric model like a nonlinear function or by using nonparametric methods as described by Loader [8]. The fitting and analysis of these more complicated change point models typically requires the help of an experienced statistician.

RONNIE WEBSTER WEST

Chernobyl Nuclear Disaster

The Incident

On April 26, 1986, Unit 4 of the Chernobyl nuclear power plant, located 100 km from Kiev in Ukraine, exploded. The explosion was caused by a combination of flaws in the reactor's design and a series of human errors during a test of the plant's ability to provide enough electrical power to operate the reactor core cooling system between a loss of main station power and the start up of emergency power. After the explosion, graphite and other materials caught fire. The Chernobyl nuclear disaster caused the death of 30 power plant workers, evacuation of thousands of people from their homes, and contamination of people, animals, plants, and soil over a wide area.

The fire burned for 10 days and released radioactive gases (see **Radioactive Chemicals/Radioactive Compounds**), condensed aerosols, and a large amount of fuel particles primarily in the former Soviet Union, but this was also witnessed throughout the Northern Hemisphere. Total ionizing radiation^a released has been estimated at 14 EBq (or 1.4×10^{18} Bq, where 1 Bq equals 1 atomic disintegration per second), including the release of 1.8 EBq of iodine-131, 0.085 EBq of cesium-137, 0.01 EBq of strontium-90, and 0.003 EBq of plutonium radionuclides [1].

The duration and high altitude reached by the Chernobyl radioactive plume resulted in approximately 200 000 km² of Europe receiving levels of cesium-137 in excess of 37 kBq m⁻². About 70% of that area was in the most affected countries of Belarus, the Russian Federation, and Ukraine (Figure 1). Deposition of radioactivity throughout these countries was variable, but was increased in areas where it was raining when the radioactive plume passed. Heavier fuel particles were deposited within 100 km of the power plant, but lighter, more volatile fission products, such as cesium and iodine, were able to travel greater distances [2].

Dose

Dose is a complex concept in radiation biology (Figure 2). Measurement of biological dose starts out

with the *equivalent* dose, which takes into consideration the biologic potency of different types of radionuclides. The *effective* dose is then obtained by multiplying the *equivalent* dose to various tissues and organs by a weighing factor appropriate to each and then summing up the products. The Sievert (Sv) is the quantitative risk that a person will suffer adverse health effects from a particular exposure to radiation.

On the basis of the availability of quantitative estimations of radiation doses, five exposed populations can be identified: (a) workers who responded first to the explosion and fire ("emergency workers"); (b) workers involved in the cleanup and recovery phase from 1986 through 1990 ("recovery operation workers" or "liquidators"); (c) inhabitants of contaminated areas in Belarus, the Russian Federation, and Ukraine ("evacuees"); (d) inhabitants of contaminated areas not evacuated; and (e) inhabitants of areas outside Belarus, the Russian Federation, and Ukraine [3].

Exposed Populations

Emergency Workers

The most exposed were emergency responders – Chernobyl plant staff and security guards, firefighters, and local medical aid personnel. During the night of the accident, about 600 workers were on site at the Chernobyl power plant. These workers were mainly exposed to external irradiation (whole-body γ irradiation and β irradiation to skin) from the radioactive cloud, the fragments of the damaged reactor core scattered over the site, and radioactive particles deposited on the skin. During the fire, measured exposure rates near the reactor core were hundreds of gray^b per hour.

Acute health symptoms were noted in 237 highly exposed emergency workers and a diagnosis of acute radiation syndrome (ARS) was confirmed in 134 of them. Since the emergency workers' individual dosimeters (or film badges) were massively overexposed to radiation during the accident, they could not be used to estimate the individual doses of γ irradiation received. Instead, complex biological dosimetry processes were used to estimate external dose in the 134 hospitalized workers.

The results of this dosimetry showed that 41 workers had mild ARS. All of them received whole-body doses from external γ irradiation in the range

Figure 1 Map of area affected by the explosion at the Chernobyl nuclear power plant [Source: <http://www.sheppardsoftware.com/images/Europe/factfile/chernobyl1.jpg>]

of 0.8–2.1 Gy. All 41 survived. Ninety three workers received higher γ doses. Of these 93 workers, 50 workers received doses between 2.2 and 4.1 Gy and only 1 died from ARS; 22 workers received between 4.2 and 6.4 Gy and 7 died; and 21 workers (13 of whom received bone-marrow transplantations) received doses between 6.5 and 16 Gy and 20 died. Skin doses from β irradiation were evaluated in eight treated workers and were found to be in the range of 400–500 Gy [1].

A total of 28 emergency workers died of ARS within the first four months after the accident. For reference, the lethal dose that would kill 50% of a γ radiation exposed population within 30 days is

about 4.5 Gy. For these severely affected workers, more than 20 radionuclides were detectable in whole-body γ measurements, but only radioiodines (iodine-131 and iodine-132) and radiocesiums (cesium-134 and cesium-137) were present in more than negligible amounts [1].

Recovery Workers or “Liquidators”

An estimated 600 000 workers – 360 000 civilians, and 240 000 soldiers – were involved in recovery and cleanup activities from 1986 to 1990. These workers were also known as *liquidators*. Recovery activities mainly involved decontaminating the

Figure 2 Sources of exposure to radioactive materials [Source: <http://www.greenfacts.org/fr/tchernobyl/images/figure-2-exposure.jpg>]

reactor block, reactor site, and roads surrounding the power plant and constructing a containment structure for the reactor known as the *sarcophagus* or *shelter object*, in addition to a settlement for plant personnel and various radio-waste repositories [4].

Among recovery workers, the most highly exposed include 5000 military personnel who worked on the roof of the reactor shortly after the accident, 1200 helicopter pilots who dumped material on the reactor to contain the fire, and others involved in risky emergency operations during the first weeks after the explosion and fire [5].

Estimates of γ irradiation doses to recovery workers, in general, show that the mean *effective* dose decreased from year to year from about 170 mSv in 1986, 130 mSv in 1987, 30 mSv in 1988, to 15 mSv in 1989 and that the average effective dose from external γ irradiation to recovery operation workers in the years 1986–1989 was about 113 mSv [1]. For reference, national regulations in the Soviet Union established a maximum allowable dose limit of 250 mSv in 1981. From 1989, the annual dose limit for civilian workers was set much lower at 50 mSv.

In addition to penetrating external radiation, recovery workers also received nonpenetrating skin doses from β irradiation and thyroid doses from internal irradiation. Unprotected skin doses were several times greater than γ doses. Thyroid doses during the first weeks after the explosion may also have been substantial.

Evacuees

Beginning within 48 h after the explosion and continuing through late 1986, about 116 000 inhabitants of villages in Belarus, the Russian Federation, and Ukraine were evacuated from the “Chernobyl exclusion zone (CEZ)”, which measures 30 km in all directions from the damaged Chernobyl reactor. Releases from radionuclides during the fire accounted for most of the exposure of the general public of which iodine-131 (half-life 8 days) and cesium-137 (half-life 30 years) were the most significant [1].

The average effective dose from external irradiation for 30 000 evacuees from Pripjat, a town only 3 km from the reactor, which was evacuated within 48 h, was estimated to be 17 mSv with a range of 0.1–380 mSv. Thyroid doses received by evacuees varied with their age (i.e., the very young were at greater risk), place of residence (i.e., the closer you lived to the reactor, the greater risk your risk), and the date of evacuation (i.e., the earlier the evacuation, the less was the risk). For Pripjat, the population-weighted average thyroid dose is estimated to have been 0.17 Gy with a range of 0.07 Gy for adults to 2 Gy for infants aged 3 years or less [1].

Estimates are that evacuation averted a collective external exposure of approximately 8260 man Sv in the 116 000 inhabitants evacuated [1]. A “man Sievert” refers to a quantity obtained by multiplying the average *effective* dose by the number of people exposed to a given source of ionizing radiation.

Inhabitants of Contaminated Areas in Belarus, the Russian Federation, and Ukraine not Evacuated

Areas of the countries of Belarus, the Russian Federation, and Ukraine are considered “contaminated” on the basis of measured cesium-137 levels. The known background level of cesium-137 from atmospheric weapons testing by the former Soviet Union in the cold war era was corrected for radioactivity decay that would have occurred in the ensuing years and the “excess” radioactivity was considered due to Chernobyl. On the basis of this type of retrospective radiologic risk estimation, any area with a radiation level of 37 kBq m^{-2} was specified as an area contaminated by the Chernobyl accident. Using this method, about 3% of the former Soviet Union is considered to have been contaminated by cesium-137 deposition densities greater than 37 kBq m^{-2} . Chiefly, these areas have been designated (a) *Central* (within 100 km of the reactor to the west and northwest), (b) *Gomel–Mogilev–Bryansk* (200 km north–northeast of the reactor), and (c) *Kaluga–Tula–Orel* (500 km northeast of the reactor in the Russian Federation) [6].

The total number of people living in areas in the three countries with cesium-137 deposition 37 kBq m^{-2} or greater in 1986 was about 5 million. During the late 1980s, about 272 000 people continued to live in areas with cesium-137 deposition levels in excess of 555 kBq m^{-2} (i.e., “strict control areas”). By 1995, outmigration, as opposed to death, from these highly contaminated areas had reduced the population to about 193 000 inhabitants [1].

Early on, the most important pathways of exposure to inhabitants of the contaminated areas came from *internal* exposure, through ingestion of cow’s milk and other foodstuffs contaminated with iodine-131, cesium-134, cesium-137, as well as *external* exposure from deposition of short-lived radionuclides (tellurium-132, iodine-131, barium-140, rubidium-103 and cerium-144, and others) and long-lived radionuclides (cesium-134 and cesium-137) [7]. Now, external exposure from cesium-137 deposited on the ground and in contaminated foodstuffs is of greatest importance while that from strontium-90 (half-life of 28 years) is of lesser importance.

The average effective dose from cesium-134 (half-life of 2 years) and cesium-137 received during the first 10 years after the accident by inhabitants of

contaminated areas is estimated to be about 10 mSv. Lifetime effective doses are predicted to be about 40% greater than those doses received during the first 10 years following the accident [1].

Inhabitants Outside Belarus, the Russian Federation, and Ukraine

Radioactive materials of a volatile nature like iodine and cesium released during the accident spread throughout the Northern Hemisphere. Radiation doses to populations outside Belarus, Russia, and Ukraine were relatively low and showed large differences depending on whether rainfall occurred during passage of the radioactive plume from Chernobyl. In fact, the Chernobyl nuclear disaster was first detected in April 1986 in the West by Swedish scientists, who were puzzled as to why their radiation monitors were getting activated.

Reliable radiation dose estimation information for populations other than those of Belarus, the Russian Federation, and Ukraine is relatively scant. Thyroid cancer studies in populations of Croatia, Greece, Hungary, Poland, and Turkey have estimated an average thyroid dose range from 1.5 to 15 mGy [8]. Studies of leukemia in populations from Bulgaria, Finland, Germany, Greece, Hungary, Turkey, Romania, and Sweden have reported an average bone-marrow dose range from about 1 to 4 mGy [8].

Late Health Impacts

Thyroid cancer in children exposed at a young age to radiation from Chernobyl has been widely accepted as causally associated with radiation exposure from Chernobyl [9]. Thyroid cancer cases per million population began rising in Belarus and Ukraine from 1990 onward, and then later in the Russian Federation. In Belarus, childhood thyroid cancer incidence rose by a factor of 100, by 200 in the Gomel region, by 7 in Ukraine, and by 8 in the Russian regions of Bryansk and Kaluga [2, 9]. The total number of thyroid cancers diagnosed in the three areas during 1986–2002 among children who were exposed to Chernobyl radiation and who were between the ages of 0–17 years is 4837 cases [9]. Cancer risk for children older than 10 years at the time of exposure seems to have reached a plateau and since 1995 the incidence rate has been decreasing for those 5–9 years

old at the time of the Chernobyl accident, while increasing for those younger than 5 years in 1986 [1]. There is still uncertainty about the existence of a causal relationship for those exposed as adults, as the adult thyroid gland is much less radiosensitive than in childhood [9].

Other than childhood thyroid cancer, no other health effects were considered to be related to Chernobyl exposure. Recently, though, data on emergency workers from the Russian National Medical-Dosimetry Registry (RNMDR) indicates some increase in morbidity and mortality caused by leukemia and solid organ cancer. Ongoing studies of noncancer risks such as cataracts, cardiovascular disease, immune system health effects, reproductive health effects, and mental and behavioral health effects are being regularly evaluated by the World Health Organization [9]. However, separating the effect of radiation from other potential factors in the causation of any late health effect seen is not a simple task. The lack of reliable individual quantitative radiation dose estimates for many in the exposed populations, the low doses of radiation outside the exposed group of emergency workers, and the existence of many other potential confounding factors makes epidemiologic detection of causal relationships between Chernobyl exposure and a particular health effect difficult to discern from the background levels of these diseases [7]. Outside of those exposed as young children and highly exposed emergency and recovery workers who are generally recognized, based on individual estimates, to be at increased risk of adverse health effects from Chernobyl-generated radiation exposure, other populations worried about adverse health effects “do not need to live in fear about adverse health effects from the Chernobyl nuclear disaster” [1].

Environmental Impacts

Large areas within Belarus, the Russian Federation, and Ukraine are still excluded from agricultural uses; and, in an even larger area, crop production, dairy production, and farm animal production, are subject to strict controls. Measurable contamination is expected to persist for 300 more years based on a factor of 10 half-lives for cesium-137. Exclusion and controls operative during the first 10 years after the accident in agricultural areas outside of Belarus,

the Russian Federation, and Ukraine have generally been lifted. Water for drinking and recreation, as well as aquatic environments for fish, have not been seen as a major contributor to total exposure from the accident despite cesium-contaminated fish being found in lakes in Sweden. Deposition in forests continues to be a problem owing to the efficient filtering characteristics of trees. For example, the trees in a forest near Chernobyl were killed by radiation and had to be destroyed and treated as radioactive waste (so-called red forest) [4].

Residual Risks

The “sarcophagus” constructed in May through November 1986 was aimed at quick environmental containment of the damaged reactor, reduction of radiation levels on the site, and prevention of further radionuclide release. However, the containment structure was built very rapidly in 1986 and has degraded since that time. Roof leaks have caused corrosion of the containment unit’s structural members and a worst-case scenario predicts a criticality incident involving leaked water interacting with the melted nuclear fuel and collapse of the sarcophagus with resuspension of radioactivity into the atmosphere. Plans are under way for a new safer containment structure, together with dismantling the existing “sarcophagus”, removing the highly radioactive fuel and decommissioning the damaged reactor [6]. Other residual risks include groundwater and atmospheric contamination from radioactive wastes stored in repository sites within the CEZ, partly buried in trenches and partly conserved in containers [6].

Most of the biologically significant radioactive isotopes released from the Chernobyl nuclear disaster had short half-lives and they have decayed away. Natural decontamination processes have reached an equilibrium and the decrease in contamination will be mainly owing to radioactive decay. Over the next hundreds to thousands of years, the only radionuclide of importance will be plutonium-239 (half-life of 24 110 years) and americium-241 (half-life of 432 years) [1].

International Collaboration

The Chernobyl nuclear disaster was considered by the former Soviet Union to have been purely an internal

matter. More than 20 years later, new thinking has emerged, as well as openness on the part of Belarus, the Russian Federation, and Ukraine, which has generated robust international collaborations. Chernobyl is now considered to be an international risk issue with several United Nations agencies and other international bodies issuing periodic assessments of the risks from Chernobyl. This new era of international collaboration has led to a productive effort to assess and manage the ongoing risks to human health and the environment from the Chernobyl nuclear disaster.

End Notes

^a. Ionizing radiation – radiation that has enough energy to remove tightly bound electrons from atoms creating an “ion pair” made up of a free electron with a negative charge and the remaining atom with a net positive charge, both of which can cause tissue destruction.

^b. Gray – a gray (Gy) refers to *absorbed* dose of ionizing radiation or the quantity of energy delivered by ionization per unit of tissue mass.

JOHN HOWARD

Clinical Dose–Response Assessment

Much of the science and practice of medicine boils down to the clinician's question of how to treat the patient that seeks his help. After investigating relevant factors and making diagnosis, the question is often which pharmaceutical agent to prescribe and at which dose. The choice of dose is a matter of striking a balance between the risk for insufficient therapeutic effect and the risk for side effects. One simple example is thrombotic prophylaxis; a drug that inhibits the blood's ability to coagulate will decrease the risk of blood clot formation, but at the same time increase the risk of bleeding. Blood clots and bleeding in the brain may both cause stroke and death. Since different patients differ in severity of disease, vulnerability, and individual preferences, the best dose may not be the same in all patients.

We start by considering the dose decision when there are good models describing the risks. This problem can be straightforward when positive and negative effects can naturally be measured on the same scale (section titled "Risk–Benefit"). However, in most situations different outcomes have to be weighted differently (section titled "Choosing the Relative Weights"). Furthermore, informed dose decisions rely on the *estimation*, based on limited data, of dose–response for the relevant effects (section titled "Estimating Dose–Response Curves"). This is sometimes complicated by complete lack of good clinical data for the drug in focus. It may be needed to rely on other sources of information to assess the risks (section titled "Good Data Do Not Always Exist"). An important question is how clinical experiments can be designed to give the best possible data upon which assessments can be based (section titled "Designing Dose-Finding Trials").

Risk–Benefit

Risk can be defined in different ways. One common definition of risk is the probability of a (specified) negative event. We can, for example, say that the risk of drug X causing an allergic reaction is less than 1 in 10 000. Risk may alternatively refer to both the probability of an event and the consequence of

this event. This latter interpretation is used in this article, where we combine the risk for unintended side effects with the risk for insufficient therapeutic effect. It is convenient to define (net) risk as the expected value of the net consequences for a specific individual or, alternatively, for a population of patients. We are interested in the relation dose–risk and, in particular, we are concerned with finding the best dose, that is, the dose that minimizes the risk.

There are often multiple effects of a drug, and the severity of side effects is often difficult to compare with the benefits. To simplify things, however, assume that the key positive and negative effects of a drug relates to mortality. Assume also that the dose–response relations for both effect and safety are known. Figure 1 shows an example of the relation between dose and deaths risks. In this example, the optimal dose is 9 mg and the resulting minimal possible mortality is 8.5%, which could be compared with the mortality of 10% at dose zero, that is, with placebo treatment. Doses above 27 mg result in higher total risks and are therefore considered more harmful than with no pharmaceutical treatment.

Implicitly, we have assumed that a death due to lack of effect is exactly as serious as a death due to an adverse effect. This is not obviously the case, perhaps for both good and bad reasons. One complication is that the time of death may be different; the positive effect may be a long-term reduction in mortality, while safety problems will occur very rapidly in some patients. A clear example, not related to dose finding, is that surgery may be associated with an almost instantaneous risk, while a successful operation may reduce the disease-related risk for many years. In such cases, the treatment option giving later deaths would be preferred if the total risk of dying from the disease or the side effect is the same for the different treatments. Giving that they are about to die, patients may also prefer to know about that in advance and get some time to prepare. Even if the consequences are identical to the patient, treating physicians and regulators may be more concerned about side effects than lack of treatment effect.

Choosing the Relative Weights

In general, a patient may experience a number of different health outcomes, and it is not sufficient only to consider mortality. Different outcomes have

Figure 1 Risk of death due to the disease (decreasing curve), due to adverse side effects (increasing curve), and total risk (U-shaped curve), as functions of the dose

dissimilar severity and should therefore be weighted differently. It may be possible to formulate the overall risk, r , as a weighted combination of the outcome probabilities,

$$r = \sum_{i=1}^m w_i \cdot P(\text{outcome } i) \quad (1)$$

where $w_1, \dots, w_m$ are the relative weights, reflecting the severity of the outcomes.

Consider an example where there are three relevant dichotomous variables, independent of each other. The intended effect of the pharmaceutical drug is to reduce the probability of the first outcome. However, there are two potential side effects, one mild and common, and one rare but serious. Figure 2 shows examples of probabilities for the three different outcomes, as functions of the dose. The relative weights of the outcomes are set to 1 : 0.1 : 5. That is the occurrence of the severe side effect is considered 5 times more serious than the first outcome, which the pharmaceutical drug intends to prevent. This outcome, in its turn, is considered 10 times more serious than the event of a mild side effect. The three risk components, $w_k \cdot P(\text{outcome } k)$, are displayed in Figure 3, together with the total risk. The dose minimizing this risk is considered optimal.

As mentioned in the section titled “Risk–Benefit”, it is complicated to compare deaths and deaths. What then about comparing a decreased risk of stroke with a common occurrence of headache and a minimal probability of a life-threatening allergic reaction? The choice of weights is difficult and often very subjective. However, it may be argued that this approach, explicitly weighting different risk

Figure 2 Probabilities of three different outcomes, as functions of dose. Intended risk reduction (decreasing curve), mild side effect (increasing high-probability curve), and severe side effect (increasing low-probability curve)

Figure 3 Risks components for three different outcomes as well as total risk (U-shape curve), as functions of dose

components, is more rational than its alternatives and also that it facilitates clear communication. A choice of dose is often inevitable, and this will implicitly mean a weighting of the risk components.

The choice of weights is discussed in general decision analysis literature [1, 2] and in a health-care setting [3, 4]. In the health-care sector, so-called quality-adjusted life years (QALYs) are sometimes used to weight together different health outcomes, especially in health economic evaluations. This concept can be very useful and facilitate a rational allocation of limited health-care resources. However, the formulation quality-adjusted life years may be perceived as offensive by laypersons. We can also see

reasons to be critical of how the concept is sometimes used. For example, the value of a life year with a certain disease is often estimated by asking the healthy public. Some health states may even be given negative values! It is occasionally suggested that individual patient preferences should formally be incorporated in a decision analysis; Protheroe *et al.* [5] gives an example from thrombotic prophylaxis. This approach has clear limitations [4]. Small probabilities are difficult to understand and evaluate for the patient, and the mere mentioning of a very rare but serious side effect may cause unnecessary worries.

Similar entities have different names in different contexts. The terms *utility*, from economics [6] and decision theory [7], or “(clinical) utility index” are often used for a weighted score of health outcomes [8]. QALYs and other preference measurement scales are often used in health economics [9]. In statistical theory the term *loss* is used [10]. The basic ideas are the same, and what we call risk can be interpreted as expected loss or the expectation of negative utility. The expected utility theory underlying much of the reasoning is described in an axiomatic way by French and Ríos Insua [11] and in a medical decision-making context by Parmigiani [4]. We have assumed the risk function to be linear, and the relevant outcomes to be independent and dichotomous. In general, the health value for a patient may be a nonlinear function of variables of different types. The risk is then the expectation of this value.

In this article we generally consider a total risk, reflecting both beneficial and adverse effects. As it is not straightforward to determine the relative importance of different outcomes, however, it is common that effect and safety are analyzed separately. Different requirements are often imposed on these aspects, and the therapeutic interval is defined to be the range of doses that fulfill both these requirements. Assume that the effect and side effect are monotonically increasing with dose. The minimum effective dose (MED) is the lowest dose for which the effect is at least a certain target value. Similarly, the maximal tolerable dose (MTD) is the highest dose for which the frequency of side effects (of a well-defined severity level) is not higher than an acceptable limit [12]. In case MED exceeds MTD, no doses are considered both safe and efficacious. In this case, and also often when the therapeutic window (MED, MTD) is narrow, the drug is not considered viable.

Estimating Dose–Response Curves

Up to now we have not considered the uncertainty in the dose–response curves. In practice, however, these curves always have to be estimated on the basis of a finite amount of data. Given a parametric model, the estimation of dose–response is a simple application of statistical regression theory [13–15]. However, the choice of model is an important issue. One should bear in mind George Box’s statement that “all models are wrong; some are useful”. When assessing risks, we are often interested in small probabilities, and the choice of model may then be especially critical for the conclusions.

Starting, however, with a continuous variable, y , a commonly used model for the dependence of the dose, d , is the $E_{\max}$ model [8, 16, 17]:

$$y(d) = \frac{E_0 + E_{\max} d^\gamma}{(d^\gamma + \text{ED}_{50}^\gamma) + \varepsilon} \quad (2)$$

where ε is the residual error, often assumed to be normally distributed with zero mean. At least three of the four parameters are readily interpretable. The mean effect at dose zero, that is placebo, is E_0 . The maximal placebo-adjusted effect is $E_{\max}$. Half of the maximal placebo-adjusted effect is achieved at a dose of ED_{50} , which therefore is a measure of the potency of the drug. Finally, the fourth parameter, γ , is related to the slope of the dose–response curve. The $E_{\max}$ model is quite flexible for monotonic dose–response curves. Nonmonotonic responses are possible, but are typically the result of a combination of effects going in opposite directions, as in Figure 1. One drawback with the full (sigmoidal) $E_{\max}$ model is that it has as many as four parameters, which are difficult to estimate with limited data on few doses. A number of models with fewer parameters, for example, the linear, loglinear and three-parameter $E_{\max}$ model (with $\gamma = 1$), can be seen as special cases of, or approximations to the four-parameter $E_{\max}$ model. Model selection may be part of the analysis, especially in exploratory settings, but usually the model is fixed in the study protocol and the resulting analysis is checked for robustness.

The logistic model (*see Logistic Regression*) is the most common model relating a covariate x to the probability p of an event:

$$p(x) = \frac{\exp(\alpha + \gamma x)}{(1 + \exp(\alpha + \gamma x))} \quad (3)$$

This model is rather similar to the $E_{\max}$ model. Assume that $\gamma > 0$, which is the case for side effects. Using the logarithm of the dose $\ln(d)$ as the argument x , the model can be written as

$$p(d) = \frac{d^\gamma}{(d^\gamma + \exp(-\alpha/\gamma)^\gamma)} \quad (4)$$

Using the reparametrization $\exp(-\alpha/\gamma) = \text{ED}_{50}$, we see that this expression is the same as that in the $E_{\max}$ model for the mean of $y(d)$ when $E_0 = 0$ and $E_{\max} = 1$. In some situations, there is a natural background incidence of an adverse event, so that $p(0) > 0$. Not all patients may be susceptible to a potential side effect, and $p(d)$ may be limited by a lower constant than 1. A four-parameter analog to equation (2) can then be motivated,

$$p(d) = \frac{p_0 + p_{\max} d^\gamma}{(d^\gamma + \text{ED}_{50}^\gamma)} \quad (5)$$

where $p_0 + p_{\max} < 1$. The probit model [18] is a common alternative to the logistic model. The models give similar results when having the same argument x , as long as the probability is not close to 0 or 1. However, extrapolations to small probabilities are not robust, and these two models may lead to considerably different predictions. Generally, the models used should not be trusted blindly.

It is wise to question assumptions and check how robust the conclusions are. As the dose–risk curve is usually flat around the optimum, small deviations from the best dose are often acceptable. The estimation uncertainty should also be reflected in the overall risk assessment. By combining the statistical uncertainties for the risk components, the uncertainty for the total risk may be deduced. Consequently, the uncertainty in the optimal dose can be investigated. The Bayesian approach [4, 19] uses probability distributions for the model parameters, and Bayesian probabilities for different outcomes are calculated by integrating over these distributions (*see Bayesian Statistics in Quantitative Risk Assessment*).

Good Data Do Not Always Exist

The risks associated with a new pharmaceutical agent become better understood over time. When developing a drug, animal and *in vitro* data give the basis for early risk assessments and for the choice of doses for the first studies in man (early phase I). Later on,

experiences from increasing human exposure justify drug administration for longer time in increasingly larger and more vulnerable groups of patients. The total risk level, in terms of numbers and severity of side effects, is considerably larger in late clinical trials (phase III) and for marketed drugs, than in small phase I trials. However, the risk for the exposed individual may be more significant for healthy volunteers in phase I than for patients in great need of a treatment. The risks should therefore be put into a context that also reflects the benefits for the individual. This is an essential component in analyzing whether a trial design is ethical [20].

In practice, the risks for healthy volunteers and patients in early clinical development are seldom quantified. Preclinical information is used together with rules of thumb and the experts' qualitative understanding. From preclinical dose-ranging trials, one often estimates a dose giving no toxic effects in a species, for example, mouse. Interspecies scaling is used to translate this dose to a corresponding dose in humans. This scaling may be based, for example, on body weight or plasma concentrations. Finally, a safety margin is added [21, 22]. Toxicological experts lead this process and determine a dose limit that is regarded as sufficiently safe for human administration. This process has generally worked well for many years, and severe side effects have been very rare in healthy volunteer studies. However, a first time in man study in London in 2006, resulted in severe adverse events in six healthy volunteers. This scandal has emphasized risks in early development and has lead to reports commissioned by the UK Secretary of State for Health [22] and the Royal Statistical Society [23]. Although not commonly done, it may be possible to quantify human risks based on preclinical data [23]. However, such predictions will rely heavily on the assumptions made. When assessing cancer risks, toxicologists often use what is regarded as a conservative assumption that the risk is proportional to the dose at low doses. This assumption is probably overly conservative for most pharmaceutical side effects [24]. It may be possible to predict some side effects (and their frequencies) early, on the basis of the pharmacological mode of action or similarities with already marketed pharmaceuticals.

During later clinical development and postmarketing, clinical data exist upon which risk assessments can be made. However, the dose–response data may be limited, and there is always a possibility that rare

side effects exist even if they have not been observed. Suppose that a clinical program has exposed as many as $N = 10\,000$ patients to the new pharmaceutical, without observing any lethal side effects. A standard confidence interval for the probability of a lethal side effect is then ranging from 0 to approximately $3/N$, that is, 3 in 10 000. For many pharmaceutical agents, treating less severe diseases, this upper confidence limit corresponds to an unacceptable risk. The solution is not to require that the clinical program size is made a magnitude larger, which would lead to unacceptable costs. What is needed is a qualitative risk assessment (are there any indications that severe side effects may occur?) and a monitoring of adverse events in clinical practice. In principle, it may be possible to translate partly subjective expert opinions about the relation between dose and risks of unseen events to quantified values through a process of elicitation [25], but the value of this for practical decision making is unclear. A discussion about estimating risks that cannot be observed directly can be found in [26].

Dose–response is not routinely addressed explicitly in postmarketing and late stage clinical trials. However, Food and Drug Administration representatives have suggested that inclusion of more than one dose in phase III could be useful for dose determination. Also, late stage trial data and postmarketing data may be combined with information from earlier phases and may occasionally motivate a change in the recommended therapeutic dose.

Designing Dose-Finding Trials

When designing a dose-finding trial, or any other clinical trial, the team has to consider both ethics and efficiency. “When considering the design of a dose-ranging study, we must first consider patient safety” to quote [27]. It is almost tautological that only ethical trials should be proposed by the sponsor, and only such trials should be approved in the mandatory review by ethical committees. The question is what constitutes an ethical trial. Much has been written about this topic and there is broad consensus that informed consent from the patient (or his guardian) is one requirement. However, it is generally not possible to lay all responsibility on the patient. It is part of the physician’s job to digest and evaluate relevant medical information; the decision cannot be

handed over solely to the patient. The most important ethical codex for clinical research is the Declaration of Helsinki [28], which states “It is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject. Physicians should cease any investigation if the risks are found to outweigh the potential benefits”. Many authors have been discussing “clinical equipoise” as a motivation for the ethics of a trial [29]. The definition is rather vague and may lead to an unclear distribution of responses. The treating physician has to take personal responsibility for the optimal treatment of his or her patient. It can therefore be argued that the physician has to evaluate whether it is better for the patient not to take part in a trial, and receive standard treatment, rather than to be randomized to one of the trial arms. This evaluation may apply a quantitative risk assessment, as described above [20, 30]. The same approach may be used by trial sponsors and ethical committees when proposing a design and evaluating a proposed design.

Within the class of designs that are considered ethical, the sponsor will search for as efficient a design as possible. A guiding principle is to use a wide dose range. It is obvious, however, that the same design will not be optimal for all dose-finding trials. First, the ethical constraints have to be acknowledged. Secondly, the design has to be placed in the full drug development context, including what is known about effect and safety before the trial, what the precise objectives of the study are, operational possibilities and restrictions, regulatory concerns, and the plans for later trials in a confirmatory phase. A good start for the design work is to model the available data [31]. As the reason for conducting an experiment is to generate information and reduce uncertainty, a critical part of the modeling work is to understand and quantify how uncertain different model components are, before the experiment, *cf.* [23]. It is also critical to consider carefully what the objectives of the trial should be, and how these objectives and the data generated in the trial would help decide whether to proceed to the confirmatory phase; and in that case, how this phase should be designed [32]. Dose-finding trial objectives are unfortunately often formulated in vague terms as e.g., “to investigate the dose–response relationship”. Unless such statements are translated into a clear quantitative objective, it is not possible to optimize the trial design. The resulting design may happen

to be reasonable, but the lack of transparency and analysis may also lead to suboptimal and unethical designs.

When there exist an agreed weighting of different outcomes (see sections titled “Risk–Benefit” and “Choosing the Relative Weights”), the main objective of a dose-finding trial is, naturally, to find the dose that minimizes the overall risk. Strictly speaking, the optimal dose is not the same in all patients, but a good design to estimate the dose that optimizes the population-average of the risk is likely to be a design that also generates useful information for individual dose optimization. To simplify the problem, assume that we have models with known uncertainty for effect and safety, a well-defined value function of these aspects, and are to choose one single dose, d^* , after the dose-finding trial. Given a proposed design and a proposed method to find the estimate d^* , it is straightforward to simulate the trial results [33] and calculate the corresponding risk. The algorithm first simulates one possible truth, that is, it selects model parameters reflecting the uncertainty in them. Thereafter, the result of the proposed trial is simulated, and the dose d^* is estimated on the basis of the simulated trial data. The risk is then calculated based on d^* and the simulated model parameter values. This simulation of risk is iterated a large number of times and the average simulated risk is calculated. Non-adaptive designs having the same sample size can often be compared directly so that the design that has lowest simulated risk is optimal within the class. The average risk will, however, decrease with the sample size. Thus, the reduced risk has to be contrasted against the sample size, cf. the literature about optimal sample size [34]. Adaptive designs, including group-sequential approaches, are generally more efficient than designs with fixed sample size. The gain, in terms, for example, of expected sample size giving the same average risk, should be contrasted to the cost and complexity of adaptations [32]. Zohar and O’Quigley [35] suggest an adaptive design for dose finding in oncology.

The books by Ting [12] and Chevret [36] deal with adaptive and nonadaptive dose-finding studies. When the risk cannot be readily defined, the objective of the trial may have to be formulated in other terms. The goal may, for example, be to find the dose giving a certain effect [32] or to estimate the dose for which the derivative of the effect with respect to $\ln(\text{dose})$ is a specified value. Phase III may be

used to fine-tune the dose; not just one dose, but two or three are included in these trials. Inclusion of more than one dose is especially useful when phase II gives limited safety data. It can be expected that the safety profile will be considerably better understood based on phase III data, and the optimal dose should therefore be chosen after receiving this information. A current hot research topic is seamless phase II + III trials, combining dose finding with a confirming phase in one single study [37]. The International Conference on Harmonisation (ICH) [38] gives a regulatory perspective on dose–response.

Coding: Statistical Data Masking Techniques

The rapid expansion of government and company databases combined with an ever growing use of the web and mobile devices has led to concomitant increase in sensitive and confidential personal data in the public domain. The US Government relies on the use of such data to identify and track terrorists and their activities. In an effort to ensure domestic security, the Homeland Security bill supports the development and implementation of advanced information technologies (e.g., data mining) for aggregating and analyzing data (*see* **Environmental Performance Index**) available both in public and private domains [1, 2]. The most recent example is the Automated Targeting System (ATS), the Department of Homeland Security (DHS) database that contains information on US citizens and foreign travelers, that is used for creating a terrorist risk profile for anyone crossing the US border [2]. The ATS data originate from multiple sources, various federal and commercial databases, and airlines' passenger name record data. The information from ATS may be shared with other DHS agencies, and airport and airlines operators. Do such data sharing and mining activities provide effective means for identification of terrorists without posing infringements on privacy of nonterrorists?

Most of the criticism of homeland security has focused on utility of data mining algorithms (*see* **Risk in Credit Granting and Lending Decisions: Credit Scoring**) in this context, and the potential high false positive rate (*see* **Microarray Analysis; Public Health Surveillance**), i.e., misidentification of individuals and their behaviors as terrorists [2–4]. Data mining algorithms require either aggregating multiple sources into a single data warehouse or mining multiple distributed databases. In both cases, record linkage methodologies and privacy protection methods play an important role [4, 5]. Traditionally, the government agencies have maintained data confidentiality by sharing data in two ways. In the *restricted access* setting only approved personnel can access data at the designated data centers. Owing to the presence of inaccurate and incomplete data, restricted access does not preclude unintended information disclosure and misidentification since most mining algorithms are based on statistical models and

assumptions that data are free of errors. An alternative method is to add a layer of privacy by changing data in some way. Allowing open access to such *masked data* offers more flexibility for mining distributed databases.

Coding broadly refers to altering the data in some way. In computer science literature, it may refer to encryption, compression, or error correction. These are relevant for cryptography and cryptanalysis, and for data and homeland security. In statistical confidentiality literature, coding encompasses various data masking techniques. These techniques generally introduce bias and variance to data. The question is how much and what kind of bias and variance is introduced and how this influences the utility of data mining algorithms and precision of identification, that is the false positive error rate. This article gives a brief overview of statistical disclosure limitation techniques for data masking, pointing out the likelihood of their use and potential impacts for data privacy. For more details on disclosure limitation and these techniques, see [6–8], and for related privacy preserving data mining techniques, see [4, 5, 9].

Statistical Disclosure Limitation and Data Masking

In statistical disclosure limitation, masking methods introduce bias and variance to data in order to minimize identity and attribute disclosure while trying to retain sufficient information needed for proper statistical inference. The goal of disclosure limitation is to examine and manage a trade-off between data utility and disclosure risk [8, 10, 11]. Data utility is a measure of usefulness of a dataset for an intended analyst. Disclosure risk measures the degree to which a dataset and its released statistics reveal sensitive information. This notion is probabilistic; as released data accumulate in the public domain, the probability of uniquely identifying members of the population increases. Vulnerabilities of public databases are evident in daily news, and they point out that neither a simple removal and replacement of identifiers nor encryption by itself is a sufficient mode of protection. An article in New York Times recently professed that a woman's identity was easily uncovered from an on-line AOL's database [12], while the Chicago Tribune claimed an easy identification of CIA employees on the basis of a web search [13].

It is, therefore, necessary to include additional levels of privacy protection.

Data masking involves transforming an $n \times p$ (cases by variables) original data matrix Z through pre- and postmultiplication and the possible addition of noise. That is, $Z \rightarrow AZB + C$, where A is a matrix that operates on the n cases, B is a matrix that operates on the p variables, and C is a matrix that adds perturbations or noise. Matrix masking can be applied to either microdata or table of counts, and includes a variety of standard approaches to disclosure limitation: (a) recodings (e.g., rounding and thresholding), (b) cell suppression, (c) data swapping, (d) perturbation, and (e) sampling (e.g., releasing subsets of data or variables – deleting rows or columns of Z), and simulation (e.g., adding rows to Z).

Rounding and *recoding* are the most commonly used methods and refer to aggregating high-risk variables into coarser values and categories. Income and money transactions are among the most data-mined characteristics and activities in counterterrorism searches. However, rounding such sensitive values to the nearest \$1000 may produce inconsistent data, i.e., the marginal totals may be hard to preserve. If rounded data are then recoded into intervals, these intervals may be biased because the distribution within an interval may not be uniform. *Blurring* is a related method, where a sensitive value in the microdata file is replaced by an average based on a group of records. The intervals may be produced *via top coding*, *bottom coding*, and/or *global recoding*. Top coding recodes the right tail of the distribution with the last k values of a variable into a new category. For example, grouping of all income values above \$200,000 is often done on US Census data. Bottom coding recodes the lower end of the distribution, while global recoding is applied to whole dataset. After tabulating the data, the cell frequencies may still be considered sensitive by some threshold rule. Agencies typically require at least three to five respondents in a cell. If this is the case, the categories may be further collapsed into a smaller set of categories, which lowers the data utility and increases the risk of false positives.

Suppression can be applied to actual microdata values, but is most often associated with suppressing cells in higher-dimensional tables. *Cell suppression* is a technique that has been widely used by statistical agencies where sensitive cells (and possibly others)

are not released. This method has been criticized for lack of generalization and statistical content for the higher-dimensional tables, and potentially false inferences. The suppressions introduce “holes” in the data and nonrandom missingness, thus creating difficulty in performing correct record linkages and statistical analyses.

Data perturbation includes methods such as *adding random noise* to the original data, and reporting the altered data or a table. In order to reduce the disclosure risk, we can add a random noise to a sensitive numerical value (e.g., add a value of a normally distributed random variable to income). A related technique for count data should provide consistency between perturbed and original tables. In *random* and *controlled rounding*, every cell is a multiple of some rounding base. In a *controlled tabular adjustment* technique, the original sensitive value in a table is replaced by another “safe but sufficiently close” value. The problem with these methods is that they change marginal distributions, which may produce faulty statistical correlations and pattern matching in data mining algorithms. Controlled rounding is designed to preserve marginal totals but, like other methods, works well only for two-way tables.

Data swapping can be considered a type of perturbation. This method chooses random pairs of respondents and exchanges a fraction of their data. The US Census Bureau uses data swapping for census tabulations, but typically swaps a small percent of data as it may impair correlations. In this setting, a search on only a few characteristics such as income, level of education, and frequency of travel, for example, can easily lead to misclassification of individuals. Another criticism of this approach is that it does not provide a general method for performing data swaps for k -way tables. Fienberg and McIntyre [6] describe swapping as a type of cell perturbation that involves trading values of some variables while holding others fixed, and generalization for k -way tables.

Most recently, agencies have shifted their focus to *sampling and simulation* techniques. *Fully synthetic* data methods use Bayesian methodology and release multiple-imputed datasets instead of the original ones. The probability of uniquely identifying an individual in such data is extremely low, but for counterterrorism purposes this will produce a high number of false positives. In related *partially synthetic* data methods, released data are composed of

the original nonsensitive and sensitive units that are replaced in a released dataset by synthetic values. Raghunathan *et al.* [14] describe methods for drawing valid inferences from such datasets. The US Census Bureau is currently working on implementing these and related methods, and on building synthetic datasets.

Related methods for contingency tables utilize Markov bases and Markov chain Monte Carlo sampling algorithms. These methods replace the original table by a random draw from the exact distribution of the tables under a log-linear model whose sufficient statistics are released marginal totals (see [9], and various articles in [7]). The released table can be considered an instance of a fully synthetic or a partially synthetic dataset produced with a special type of data swapping. The agency can also opt for releasing *partial information* by releasing only the relevant margins instead of a full table. To assess disclosure risk for the original table, these methods use undirected graph theory in connection with log-linear models as a framework to compute bounds on cell entries given a set of released margins. They also generalize the Bonferroni–Fréchet–Hoeffding bounds for cell entries in k -way contingency tables given such partial information. Alternatively, these bounds can be used as recoding intervals for released data providing another form of partial or fragmentary data release. Fienberg and Slavkovic [9] extend these results to bounds, simulations, and samplings from the posterior distribution of tables that satisfy other constraints (e.g., conditional probabilities and odds ratios), and tie them to mining of association rules.

Some argue that “selective revelation” techniques may significantly reduce privacy concerns [4]. A selective revelation is a method that attempts to separate “transactional” data (e.g., ticket purchase, money transfers, etc.) from identity, and reveals information incrementally. Since the bounds are calculated by accounting for the collective on the basis of partially released information, a potential exists to dynamically update the safe releases, and incrementally reveal identities as purported by selective revelation.

The importance of simulation/sampling methods is that we can generate distributions of all possible tables given the margins and other statistics, and hence establish a probabilistic framework for disclosure assessment and statistical inference. Risk of identification in such datasets is minimal. The utility is tied to the family of posterior predictive

distributions from which data have been drawn. However, what effects these methods have on record linkage and privacy preserving data mining methods is still unclear; that is, how will information from various databases be combined, and how will this affect the false positive error rate and profiling?

Conclusions

This article has outlined some data masking techniques as a way of recoding data to protect privacy. Most of the aforementioned masking methods introduce bias and variance to data, and create sparse, partial, and fragmentary data. Such data present methodologically hard statistical problems and can cause errors in naive data mining algorithms whose main goal is to uncover patterns in data. Along with the low prevalence of terrorists in a large pool of nonterrorists, these methods exacerbate the already present issues of producing many false positives and posing infringements on privacy.

Effective search for terrorists without infringement on privacy is almost impossible. It is a “needle in a haystack problem” as (a) the volume of available data is enormous and (b) the relevant records are often hidden within vast amounts of irrelevant data [15]. The solution involves complex interplay between confidentiality promises made to the respondents and the government’s need for fighting terrorism. It requires work on the optimization problem of maximizing available (“correct”) information needed for identification of terrorists, but minimizing the false positives and the risk of undesirable data disclosure. There has to be a careful consideration of the data context and analysis goals. This is a dynamic system, and as new technologies emerge, the current privacy practices (e.g., statistical, legal, ethical) are challenged and require multidisciplinary work. Every method requires a careful cost–benefit analysis, a decision-theoretic solution, and merging of different tools from statistics, privacy preserving data mining, and cryptography and cryptanalysis.

Cohort Studies

Cohort studies provide the most comprehensive approach for evaluating overall patterns of health and disease. Every epidemiologic study should ideally be based on a particular population's experience over time. The cohort design has the advantage, relative to other study designs, that ideally it includes all of the relevant person-time experience of the population under study, whereas other study designs, such as case-control and cross-sectional studies, involve sampling from that experience. In general, cohorts are defined by the nature of their exposures. We illustrate the design and analytical features of cohort studies using examples primarily from studies of occupational and environmental exposures, since these are the exposures most commonly involved in quantitative risk assessment. Nevertheless, the basic principles also apply to other types of cohort studies.

Basic Cohort Design

In a cohort study, an investigator may follow a population into the future, i.e., a *prospective cohort study*, or may follow an historical cohort to the present, i.e., an *historical cohort study* (also known as *retrospective cohort study*). Some studies combine features of both prospective and historical designs.

For studies investigating environmental exposures, a cohort is usually based on a particular community (or a sample of the community) that is followed (usually prospectively) over time. This usually requires a special survey to be conducted at the start of the follow-up period. Follow-up may then involve either repeated surveys, or linkage with routine records (e.g., hospital admissions and mortality records). For example, Grandjean *et al.* [1] studied a cohort of 1022 consecutive singleton births in the Faroe Islands, and assessed prenatal methylmercury exposure from the maternal hair mercury concentration; 917 of the children then underwent detailed neurobehavioral examination at about age 7 years.

Alternatively, a cohort can be constructed from routine population records for the entire population of a particular area, without contacting each person individually. For example, Magnani *et al.* [2] studied incident cases of pleural malignant mesotheliomas in the town of Casale Monferrato during

1980–1991. The population “at risk” was estimated from population statistics for the local health authority area. The analysis excluded incident cases for which there was some suggestion of occupational or paraoccupational exposure in order to estimate the general population risks for nonoccupational exposure from living in the vicinity of the plant.

Cohorts may also be constructed on the basis of occupational exposures, (*see Occupational Cohort Studies*) i.e., the cohort members are defined according to where they work rather than where they live. One option is to include “all workers who worked for at least 1 month in (a particular) factory at any time during 1969–1984” (e.g. [3]). Perhaps a more common option is to include workers from multiple plants operated by different companies, but engaged in the same industrial processes. For example, Demers *et al.* studied 27 464 men employed by 14 sawmills for 1 year or more between 1950 and 1995. International studies, which combine occupational populations from similar facilities located in different countries, are extensions of this approach (e.g. [4]). The advantage of restricting the cohort to workers from one facility, is that characterization of exposures may be more consistent and precise when work history and environmental data are obtained from a single source. However, pooling cohort members from multiple facilities may be necessary to increase study size, especially when outcomes of interest are rare. When a specific exposure is of interest, cohorts can be pooled based on their shared exposure patterns in multiple workplace or environmental settings. The international collaborative historical cohort study of workers exposed to phenoxy herbicides, which focused primarily on soft tissue sarcomas and non-Hodgkin's lymphoma [5], is a good example.

A *fixed cohort* is one in which the cohort is restricted to workers employed (or people living in the community) on some given date. By contrast, a *dynamic cohort* includes all workers who would be enumerated in a fixed cohort and workers hired subsequently (or people who moved to the community subsequently). Fixed and dynamic cohorts are sometimes referred to as *closed* or *open* cohorts, respectively. The choice of a fixed or dynamic cohort may be dictated by the availability of data or by special exposure circumstances that occurred during some particular (usually brief) time period. Ott and Zober's [6] study of a group of workers exposed

to dioxin during an industrial accident at a German trichlorophenol manufacturing plant, or studies of A-bomb survivors [7], are examples where a fixed cohort would be preferred – although in the latter instance, concern about possible effects on offspring of those exposed has also led to the establishment of a dynamic cohort of their children who were born after the event [8].

In community-based cohorts, comparisons are usually made internally between study participants exposed and those not exposed to a particular risk factor, e.g., high *versus* low arsenic intake in well water (see **Water Pollution Risk**) [9]. In studies of occupational populations, an internal comparison may also be possible, e.g., by comparing workers with high carbon black exposure to those with low carbon black exposure [10]. However, in some instances this may not be possible because good individual exposure information is not available or because there is not sufficient variation in exposure within the population (e.g., because everyone who worked in the factory had high exposure). In this situation, an external comparison may be made, e.g., with national or regional death rates or cancer registration rates.

For practical reasons, very few cohort studies address lifelong exposure and disease experience. Instead, cohort studies are usually restricted to time periods for which such information can be obtained; thus health effects that occur outside of this time period (e.g., those with a long latency period) may not be detected. Additionally, an inappropriate choice of comparison groups (e.g., national populations compared to worker cohorts) can lead to confounding. The healthy worker effect, which is a manifestation of the latter type of bias, poses a major problem for occupational cohort studies involving external comparisons [11]. Several approaches for reducing bias caused by the healthy worker effect are available. One strategy is to compare disease rates among the workers in the cohort with rates in an external reference population also consisting of employed (and retired) workers, but such information is rarely available. Alternatively, the reference population might be selected from among employees in an industry (or community) other than the one under study. For example, in their study of cardiovascular diseases among viscose rayon factory workers, Hernberg *et al.* [12] selected as a comparison group workers at a paper mill not exposed to the suspected etiologic factor, carbon disulfide.

Another approach is to use an internal reference population, consisting of some segment of the full study cohort, usually assumed to be nonexposed to the hazardous agents of concern [13]. This approach may not eliminate bias from the healthy worker effect, but will usually reduce it [14]. Stratification on employment status (active *versus* inactive) [15] and on length of follow-up [14] may also help minimize healthy worker effect bias in internal comparison analyses. An additional advantage of using an internal reference population is that similarity of data quality is anticipated for all groups compared.

Cohort Enumeration and Follow-up

Cohort Enumeration

In a community-based cohort study, enumeration of the cohort usually requires an initial community survey, followed by prospective follow-up. The enumeration of an historical occupational cohort usually requires assembly of personnel employment records containing dates of first and last employment and the various jobs held, with their associated dates. In occupational studies, short-term transient workers may be excluded since they are often difficult to trace, and may have atypical lifestyles that make them noncomparable to longer-term workers [16]. For example, Boffetta *et al.* [17] found markedly elevated mortality rates from external causes of death (e.g., motor vehicle accidents), but only slight differences for cancer and ischemic heart disease, among workers employed for less than 1 month compared to longer-term workers in two international cohorts of workers in the man-made vitreous fiber and reinforced plastics industries. In dynamic community-based studies of environmental exposures, short-term residents may be excluded for the same reasons.

Follow-up

In some instances, particularly in community-based studies, follow-up may involve regular contact with the study participants, including repeated surveys of health status. Perhaps more commonly, follow-up may be done by routine record linkage. For example, study participants may be followed over time by linking the study information with national death records, or disease incidence records (e.g., a national

cancer registry), as well as with other record systems (e.g., social security records, drivers license records) to confirm vital status in those who are not found to have died during the follow-up period.

Although most developed countries have complete systems of death registration, and it is easy, in theory, to identify all deaths in a particular cohort, this may not be so straightforward in practice. For example, many countries do not have national identification numbers and record linkage may have to be done on the basis of name and date of birth using record linkage programs to identify “near matches”. A further problem is that some countries do not have national death registrations, and these may be done on a regional or state basis instead, making it necessary to search multiple registers. Moreover, just because someone has not been identified in death records, this does not mean that they are still alive and “at risk” since they may have emigrated or may not have been identified in death registrations for some other reason. It is therefore desirable to confirm that they are alive using other record sources such as drivers license records, voter registrations, social security records, etc. [11].

Table 1 summarizes the various sources of data on vital status, cause of death, and disease incidence. If coding the cause of death is not performed routinely by national or regional health statistics agencies, then a copy of each death certificate should be obtained and coding should be performed by a nosologist trained in the rules specified by the International Classification of Diseases (ICD) volumes compiled by the World Health Organization (<http://www.who.int/classifications/icd/en/>). Revisions to the ICD have been made over the years, and changes in coding for some causes may influence the mortality findings of the study. If a comparison is being made with national mortality rates, then it is important that the cohort study deaths should be coded using the same ICD revision as was used for national data during the same time period. Death certificates in most countries record underlying and contributing causes of death. The underlying cause is generally of most interest in occupational mortality studies, although information on contributing causes and other significant medical conditions may be useful for identifying some health outcomes (e.g., diabetes, hypertension, pneumoconiosis) [18, 19].

Data on disease incidence, rather than mortality, can be obtained provided that there are

Table 1 Sources of vital status and disease occurrence^(a)

Source	Data supplied
Social Security Administration (US)	Vital status, date and location of death
National Death Index (US)	Date, location, cause of death
Motor vehicle bureaus	Alive status inferred from license or citation issuance
Voter registration lists	Alive status, inferred
Credit bureau listings	Alive status, inferred
National Office of Pensions and Insurance (UK)	Vital status, location, date of death
Population-based disease registries (Sweden, Finland, among others)	Vital status, cause of death, incidence of specific diseases, location, date of occurrence
Vital statistics bureaus	Death certificates, birth certificates
National insurance and benefits offices	Alive status (inferred)
Company medical and insurance claims	Death certificates, illness and injury occurrence
Unions and professional societies	Death certificates, illness and injury occurrence

^(a) Reproduced from [11]. © Oxford University Press, 2004

population-based disease registers or that special incidence surveys have been conducted on the workforce. National registries are only available in a few countries, but there are a number of population-based regional cancer registries around the world [20], such as the Surveillance, Epidemiology, and End Results (SEER) cancer registries in the United States [21].

In a cohort mortality study, there are two types of participants for whom vital status information may be missing [11]. The first are participants of unknown vital status. One should include all of the available information in the analysis by counting person-years of observation for unknowns up until the dates of last contact, typically the dates of termination from the industry (or the dates of leaving the community). The assumption in this approach is that there is no systematic bias resulting from the loss of information on the subsequent period, i.e., that the association between exposure and disease in

the “missing data” is the same as that in the cohort as a whole.

The second category of study participant with missing information comprises those with deaths of unknown cause. This situation usually arises when death certificates cannot be located, but may also occur when cause of death information on some death certificates is judged by the nosologist to be inadequate for coding. The usual approach is to create an unknown cause of death category because this approach does not require unverifiable assumptions about the distribution of cause of death among the unknowns.

Data Analysis

Person-Time Analyses

An understanding of the analytic techniques used in cohort studies requires an appreciation of the distinction between disease risks and rates. A *risk* is the probability of developing or dying from a particular disease during a specified time interval. Thus, if we conduct a 10-year follow-up on a cohort of 1000 people, and we have no losses to follow-up, and we observe 30 deaths, then the 10-year risk of death is 30/1000 people.

A second approach is to compute the number of newly occurring, or *incident*, cases during the time interval of follow-up per number of *person-years of observation*. This quantity is a disease *rate* [22]. The value of computing rates, rather than risks, in cohort studies is that rates take into account the person-time of observation, which is likely to vary between cohort members when there are losses to follow-up, when participants die from other diseases than the outcome under study, or when the cohort is dynamic.

Computation of person-time data has become standard practice in dynamic occupational cohort studies since the 1950s [11]. Each subject alive at the beginning of follow-up contributes person-years of observation until he or she either develops or dies from the disease of interest, dies from another cause, or the end of follow-up occurs. When a minimum employment (or residency) duration of x years is imposed in a cohort (or community-based) study, then follow-up for each participant should be started either at the date at which x years of service (or residency) had been attained, or at the date of cohort enumeration, whichever occurred later. The reason

for this shift in follow-up commencement date is that, by virtue of the cohort inclusion criterion, it is known that each participant survived for at least x years. Thus, his first x years are effectively free from risk. Failure to account for these x years as “risk free” would tend to underestimate disease rates in the cohort. Thus, if a study involves follow-up for the period January 1, 1980 to December 31, 2005, and a person started work (or moved into the area) on July 7, 1993, and there is a 1-year minimum duration of employment (or residency) criterion, then follow-up for this participant would commence on July 7, 1994 – unless they had left work (or moved) in the meantime, in which case they would be excluded from the study, unless they subsequently returned and eventually met the minimum employment (or residency) criterion.

Similarly, follow-up for each cohort member finishes when they die, develop the outcome of interest (in an incidence study), are lost to follow-up, or the overall study follow-up finishes, whichever date is earliest. Thus, if a study involves follow-up for the period January 1, 1980 to December 12, 2005, and a person died, developed the outcome of interest (in an incidence study), or was lost to follow-up on July 7, 2003, then follow-up for this participant would finish on this date.

Thus, length of follow-up and length of employment (or length of residency) are not usually identical – someone may have accumulated many years of employment (or residency) if they commenced work (or moved to the area) before the study follow-up commenced.

Stratified Analysis

The epidemiologic method for summarizing person-years across age and calendar years is to stratify the cohort’s collective person-years into a cross-classified distribution [11]. Age and calendar year are the two most important stratification variables because many diseases are strongly age-related, and population rates (even within narrow age categories) vary over time [23]. Length of employment, age at first employment, time since first employment, and employment status (active/inactive) can also influence disease rates, primarily as confounders or effect modifiers of the associations between health outcomes and the exposures of interest. Person-years accumulation is therefore accomplished by summing

each cohort member's contribution to every attained category, where age and calendar year strata jointly specify the categories.

To illustrate the method of stratification, consider a worker for whom follow-up commenced on January 1, 1987, at which time he/she was exactly 28 years. He/she would contribute 2 person-years to the 25–29 year age and 1985–1989 calendar year jointly classified stratum, then 1 person-year to the 30–34 year age and 1985–1989 calendar year stratum, then 4 person-years to the 35–39 and 1990–1994 stratum, and so on. The process of stratification of person-years can be extended to also include other factors in addition to age and calendar year (e.g., ethnicity, socioeconomic status, duration of follow-up, cumulative exposure) by apportioning person-years into a K -dimensional matrix, where K represents the number of stratification variables. The numbers of person-years in any cell of such a matrix will diminish as the number of variables and associated categories increase. Fortunately, there are sophisticated computer programs that can accommodate person-years counting for these more complex, yet typical, situations [11].

Stratum-specific incidence or mortality rates are computed by dividing the cohort's total number of cases (deaths) by the number of person-years. However, when studying rates for many different diseases among a cohort, the stratum-specific rates may be highly unstable because of small numbers of cases or person-years in individual strata, even when the cohort is relatively large.

Table 2 gives the general layout for data from a cohort study. This is the data layout for the *crude* table when there is no stratification made on age, calendar year, or any other potentially confounding variable. The same basic data layout is used for each stratum in a stratified data presentation; here, the cell entries (a , b , N_1 , N_0 , M , and T) would be indexed by subscripts such as i , j , k , etc., denoting levels of the various stratification factors. For example, if stratification were performed on age at 5 levels and calendar year at 3 levels, then there would

be $5 \times 3 = 15$ age/calendar year-specific strata. Age might be indexed by $i = 1, 2, 5$, and calendar year by $j = 1, 2, 3$. Thus, the data table for the second age-group and first calendar year stratum would be a_{21} , b_{21} , and so forth.

The standard measure of effect in cohort studies is the rate ratio, i.e., the ratio of the incidence rate (or mortality rate) in the exposed (study) population to that in the nonexposed (comparison) population. The two approaches that can be taken to summarize rates across strata of a potential confounder (e.g., age), while maintaining the unique information contained within strata (stratum-specific rates), are *standardization* and *pooling* [22].

The basic feature of a *standardized* rate (SR) is that it is a weighted average of stratum-specific rates. A general expression for an SR is given by

$$SR = \frac{\sum_i W_i I_i}{\sum_i W_i} \quad (1)$$

where i indexes the strata; the W_i are the stratum-specific weights; and the I_i are the stratum-specific incidence (or mortality) rates. The ratio of standardized rates (RR_s) is expressed as:

$$RR_s = \frac{\sum_i W_i (a_i / N_{1i})}{\sum_i W_i (b_i / N_{0i})} \quad (2)$$

Note that the numerator of expression (2) is the SR in the exposed population, and the denominator is the SR in the reference population.

In computing a standardized mortality ratio (SMR), the W_i are taken from the confounder distribution of the exposed population (i.e., $W_i = N_{1i}$), and expression (2) reduces to:

$$SMR = \frac{\sum_i a_i}{\sum_i N_{1i} (b_i / N_{0i})} \quad (3)$$

The SMR is thus the ratio of the sum of the observed cases in the exposed population, relative to the sum of the expected numbers in the exposed population, where the expected numbers are based on rates in the reference population.

Table 2 Data layout for a cohort study using rates and person-years

	Exposed	Nonexposed	Total
Cases	a	b	M
Person-years	N_1	N_0	T

Approximate confidence interval estimation for the SMR (CI_{SMR}) can be obtained from the following formula [22]:

$$CI_{SMR} = e^{\ln(SMR) \pm Z(SD(\ln(SMR)))} \quad (4)$$

where $SD(\ln(SMR))$ is the standard deviation of the natural logarithm of the SMR, defined as under:

$$SD(\ln(SMR)) = 1/Obs^{0.5} \quad (5)$$

Obs is the numerator of the SMR and Z is the standard normal deviate specifying the width of the confidence interval (e.g., $Z = 1.96$ for a 95% interval).

The alternative method is exemplified by the standardized rate ratio (SRR) [24]. One variant of this involves taking weights from the confounder distribution of the reference population (i.e., $W_i = N_{0i}$), in which case, expression (2) becomes

$$SRR = \frac{\sum_i N_{0i}(a_i/N_{1i})}{\sum_i b_i} \quad (6)$$

The SRR is therefore the ratio of the number of expected cases in the reference population, based on rates in the exposed group, to the number of observed cases in the reference population.

Another general method of summary rate ratio estimation is *pooling*, which involves computing a *weighted average of the stratum-specific rate ratios* (rather than the ratio of weighted averages of stratum-specific rates, as in expression (2)). In this case, RR_s takes the form:

$$RR_s = \frac{\sum_i W_i(a_i/N_{1i})/(b_i/N_{0i})}{\sum_i W_i} \quad (7)$$

The most common choice of weights is that given by the Mantel–Haenszel [25] method which uses weights of $b_i N_{1i}/T_i$ [22]. With these weights, expression (7) becomes:

$$RR_{M-H} = \frac{\sum_i a_i N_{0i}/T_i}{\sum_i b_i N_{1i}/T_i} \quad (8)$$

An approximate standard error for the natural log of the rate ratio is given by Greenland and Robins [26]

$$SE = \frac{[\sum M_{1i} Y_{1i} Y_{0i}/T_i^2]^{0.5}}{[(\sum a_i Y_{0i}/T_i)(\sum b_i Y_{1i}/T_i)]^{0.5}} \quad (9)$$

Thus, an approximate 95% confidence interval for the summary rate ratio is then given by

$$CI_{RR} = RRe^{\pm 1.96SE} \quad (10)$$

When the rate ratio is constant across all strata of the confounder, all three estimators (SMR, SRR, and RR_{M-H}) give the same result. This can be shown by assuming that the rate for the exposed group is equal to some multiple, M , of the rate in the reference population, i.e., $a_i/N_{1i} = M(b_i/N_{0i})$. Substitution into expression (2) (for the SMR or SRR) or expression (5) (for RR_{M-H}) yields: $RR_s = M$, in each instance.

The analytic methods based on stratified analyses that have been presented above are adequate for many occupational and environmental epidemiology studies, particularly those in which a simple exposed *versus* nonexposed classification is used. However, stratified analyses may not be feasible if there are multiple exposure categories or more than two or three confounders; it is then necessary to use multiple regression. In a cohort study, the appropriate model form is *Poisson regression* which is an extension of the simple analysis of rates (SMR, SRR, or RR_{M-H}) described above [27]. This is described in detail in standard texts such as Rothman and Greenland [22].

Strategies of Data Analysis

The first research question addressed in a cohort study is whether or not the rates of various diseases and injuries observed for the study cohort are different from rates found in a comparison population, which is presumed to be nonexposed to the agent(s) of concern. Table 3 summarizes the findings of a study by Wellmann *et al.* [10] of mortality in German carbon black workers employed for at least 1 year at a carbon black manufacturing plant, between 1960 and 1998. Follow-up was for the period 1976–1998. It shows that the cohort experienced an excess risk of mortality from all causes with 332 deaths observed, compared with 275.5 expected ($SMR = 1.20$, 95%

Table 3 Standardized mortality ratios (SMR) for all cause mortality and lung cancer mortality in German carbon black workers^(a)

Cause of death	Observed	Expected	SMR	95% CI
All causes	332	275.5	1.20	1.08–1.34
Lung cancer	50	23.0	2.18	1.61–2.87

CI 1.08–1.34); there was also a specific excess of lung cancer deaths, with 50 observed compared with 23.0 expected ($SMR = 2.18$, 95% CI 1.61–2.87).

Subcohort Analyses

The second level of cohort data analysis is a comparative examination of disease rates between subcohorts defined on the basis of their exposure experience, provided that job and/or exposure level data are available or can be reconstructed for the cohort. The simplest measure of exposure is the number of years of employment in the industry. An example of this approach, from the study of Wellmann *et al.* [10] is shown in Table 4. Person-years (and deaths) were accumulated by categories of years of employment, with study participants moving through the various categories over time (just as they are moved through age-groups and calendar periods). This involved an internal Poisson regression analysis in which those person-years and deaths which occurred in the 1–5 years of employment category were taken as the reference (there were no person-years accumulated for those with less than 1 year of employment as this was an inclusion criteria for the study).

The next level of analysis involves obtaining some information on actual exposures rather than simply the number of years that the study participants were exposed. In community-based studies, exposure estimates may be based on street address and length of residence, or may be based on personal exposure measurements. For example, Bertazzi *et al.* [28] studied the population of the Italian town of Seveso which was exposed to dioxin (see **Health Hazards Posed by Dioxin**) following a factory accident in 1976. Three contamination zones were delimited (Zones A, B, and R) based on their proximity to the plant and whether they fell under the natural fallout path of the chemical cloud. Thus, study

participants were categorized according to where they were living at the time of the accident, but this categorization was later confirmed by measurements of dioxin Tetrachlorodibenzo-*p*-dioxin (TCDD) concentrations in soil and in the blood of selected residents.

In occupational studies, characterization of workers into groups defined on the basis of process division in the plant or similarity of jobs and tasks is especially valuable when exposure intensity data are limited or nonexistent. The simplest approach is to categorize each worker into only one grouping, e.g., their longest held job. However, this can sacrifice information on other jobs/exposures. The solution is to make full use of all the person-time information available [11], by carrying out a separate analysis for each job category. The simplest such analysis is a comparison of the disease rates of workers who have ever worked in a particular job category with those of workers who have never worked in that category. Each analysis thus involves all of the person-time experience and cases (or deaths) in the study. An example of this approach, from the study of Wellmann *et al.* [10] is shown in Table 4. Separate analyses were conducted for employment (for at least 1 year) in “lamp or furnace black”, “gas black”, or the “preparation plant”; each of these analyses involved all of the deaths (and all of the person-years) in the cohort, and the data were classified according to whether each participant (at the time of the person-year in question) had accumulated, or not accumulated, at least 1 year of employment in the relevant job category. Once again, this involved an internal analysis in which those people who had not accumulated at least 1 year of employment for the particular job title (at the time of the person-year in question) were taken as the reference.

A refinement on this approach is to rank job categories with respect to exposure intensity for the agent(s) of interest [11] (or areas of residency which are similarly ranked, as in the case of the Seveso study [28]). *Ordinal rankings* can be made either on the basis of informed judgment or with reference to exposure measurements. Under such a scheme, jobs are grouped according to polychotomous ordinal rankings, such as “low”, “moderate”, and “high.” This is illustrated for the study by Wellmann *et al.* [10] in Table 4 for the category of “heavily exposed jobs”.

Cumulative Exposure

When quantified exposure data are available for all or most workers, either by means of linkage of job and work area data to employment history information or, less often, from personal monitoring, it will be possible to define subcohorts on the basis of maximum exposure intensity or with respect to cumulative exposure levels. Many occupational diseases are strongly related to *cumulative exposure* which is simply the summed products of exposure

intensities and their associated durations. Typical examples of cumulative exposure in occupational studies are milligrams of dust per cubic meter $\times$ years, fibers per milliliter $\times$ years, and parts per million $\times$ years for chemical exposures. In a community-based study, cumulative exposure might be based on estimated exposure levels (e.g., levels of arsenic in well water) $\times$ years of residency.

An occupational example of this approach, from the study of Wellmann *et al.* [10] is shown in Table 4. Study participants were classified according

to their average annual carbon black exposure, and this was combined with information on years of employment to yield estimates of cumulative carbon black exposure. Once again, this involved an internal analysis in which study participants were moved through exposure categories over time, and those person-years (and deaths) which occurred in the category of 0–5 units of cumulative carbon black exposure were taken as the reference. The analyses indicated that, although there were overall excesses of all causes mortality and lung cancer mortality in this cohort, these were not associated with average or cumulative levels of carbon black exposure.

Latency and Induction Time

For all diseases or injuries, there are requisite time lags between exposure to etiologic factors and clinical manifestation. In the extreme case of an acute episode, such as an electrocution following exposure to high voltage or eye irritation from a noxious gas, the time lag is effectively nil because the response is virtually instantaneous. However, many occupationally related diseases are delayed effects of exposure, where the time lag may range from hours or days (e.g., pulmonary edema) to decades (e.g., cancer).

Latency is the term often applied to the time interval between exposure and disease manifestation or recognition. However, Rothman [29] defines latency as the period from disease initiation to manifestation. This definition is consistent with the idea that there is some period of time when the disease exists in a “hidden” state in an individual. A related concept is *induction time*, which can be defined as the period

from first exposure to an agent or collection of agents to disease initiation [29]. The induction time will of course vary, depending on the nature of the exposure and disease, as well as on individual responses to exposure. Many occupational and environmental exposures can be considered to be chronic, extending over periods of years or decades, but may also be intermittent within the period of exposure. Intermittent exposures, while relevant for induction of some diseases, will not be discussed here so as to simplify matters. Thus, while we cannot usually estimate induction time, we can determine the interval from exposure onset to disease manifestation or recognition. Rothman [29] refers to this interval, which is the sum of induction and latency times, as the *empirical induction time*.

Several methods for taking into account induction and latency have been applied [11]. The most valid and appropriate technique is to *lag exposures* by some assumed latency interval (y), such that a worker's current person-year at risk is assigned to the exposure level (either intensity, duration, or most commonly, cumulative exposure) achieved y years earlier [30, 31]. Consider an example using cumulative exposure as the exposure index. If by age 40 a worker had accumulated 25 cumulative exposure units, and by age 50 his cumulative exposure was 45 units, then under an assumed latency interval of 10 years, his person-year at risk for age 50 would be assigned to the 25 cumulative exposure unit level. Exposure lagging has the particular advantage of including the entire enumerated cohort and all members' complete exposure histories, unlike the other

Table 5 Poisson regression analyses of cumulative occupational arsenic exposure and circulatory disease mortality, by 0, 10, and 20-year lag periods^(a)

^(b) Reference category

methods described above which sacrifice information either by subject exclusion or exposure truncation.

Table 5 gives an example of exposure lagging from a study by Hertz-Picciotto *et al.* [32] of circulatory disease mortality in a cohort of 2082 white males employed for 1 year or more in a copper smelter in Tacoma, Washington during 1960–1964. Follow-up covered the period 1940–1976. The use of lagged exposures increased the relative risks of circulatory disease mortality for all levels of exposure compared with the baseline level, supporting the hypothesis that cumulative arsenic exposure increases circulatory disease mortality.

An extension of the lagging approach to latency analysis is to estimate effects related to exposures that occur during discrete-time periods, or *time windows* [31]. Thus, for example, it might be considered that, for some particular health outcome, both the most recent and most distant exposures were probably less related than exposures during a critical time window. A good illustration would be exposure effects that are linked with birth defects during particular periods of fetal development [33]. The analysis of time windows is performed in a similar manner as lagging, except exposures during the assumed etiologically unrelated recent and distant periods are discounted. The analysis should maintain the temporal relation with follow-up, such that person-years are distributed appropriately to the moving time window of interest [34].

Discussion

We have described methods for assembling and following community-based and occupational cohorts, and for making disease rate comparisons with external and internal reference populations. These comparisons permit evaluations of the cohort's overall disease experience and associations with various exposures. What may not be evident from the discussion is the scope of work required to conduct an occupational or environmental cohort study successfully. These studies typically involve the efforts of epidemiologists, environmental scientists, occupational hygienists, biostatisticians, computer programmers, and clerical staff. The magnitude of the effort will depend on the size of the cohort studied and on the volume and complexity of the exposure data to be assimilated. For example, vital status tracing and

cause of death ascertainment for a cohort of 5000 people is seldom completed in less than 1 year, and a thorough reconstruction of exposures and analysis of data might require another 1–2 years. These comments pertain primarily to historical cohort studies. Prospective cohort studies are usually substantially more expensive and time consuming.

There are, however, particular advantages to cohort studies. First, by design, they include all or as many members of the dynamic cohort as can be identified and traced. There is a statistical precision advantage to this approach, but more importantly, cohort studies offer the broadest available picture of the health experience of a workforce because rates for multiple health outcomes can be examined. More intensive investigations of exposure–response associations are best done for a selected subset of health outcomes of *a priori* interest and those discovered to occur at excessive rates in the cohort.

The second, less obvious, advantage of cohort studies is that the process of enumerating a cohort makes the investigator more aware of the particular characteristics of the population under study, e.g., the ethnic, gender, and social class groups most heavily represented, and the subgroups of the cohort most completely traced. Other study designs that include only samples of the cohort do not offer as complete an assessment of the exposure and health experience of a population. Finally, phenomena characteristic of occupational populations, such as bias resulting from the healthy worker effect, are examined most directly in cohort studies.

Collective Risk Models

Individual and collective risk models in actuarial science are often referred to as *models for aggregate claims* (see **Comonotonicity; Longevity Risk and Life Annuities; Reinsurance**) that arise from an insurance portfolio over a fixed period of time. If the insurance portfolio is closed, that is, the number of policies in the portfolio is fixed and no replacement is allowed, then the aggregate claims may be expressed as

$$S_n = X_1 + X_2 + \cdots + X_n \quad (1)$$

where n is the number of policies, and for $i = 1, 2, \dots, n$, X_i is the claim amount over the period from the i th policy. If there is no claim, $X_i = 0$. It is normally assumed that the claim amounts $X_1, X_2, \dots, X_n$ are mutually independent but they are not identically distributed. The above model is referred to as the *individual risk model*. The evaluation of the model involves the use of convolution techniques (see **Ruin Probabilities; Computational Aspects; Operational Risk Modeling**). In contrast with the individual risk model, the collective risk model does not make direct reference to the risk characteristics of the individual members of the portfolio when describing the aggregate claims experience of the whole portfolio itself. To model the total claims of a collection of risks over a fixed (usually prospective) period of time, the collective approach incorporates both claim frequency and claim severity components into the probability distribution of the aggregate.

To substantiate, let N be a counting random variable representing the number of claims experienced by the portfolio over the predetermined time period, and let Y_i be a random variable representing the amount of the i th claim to occur within this same period. Then the total or aggregate claims over the period is given by the random sum S where

$$S = Y_1 + Y_2 + \cdots + Y_N \quad (2)$$

with $S = 0$ if $N = 0$. For mathematical tractability, it is normally assumed that $\{Y_1, Y_2, \dots\}$ is a sequence of independent and identically distributed (iid) non-negative random variables independent of N . This assumption implicitly requires (among other things) that the time period of interest be short enough so

that temporal variation in claims experience may be ignored. By conditioning on N , it follows from equation (2) that the expected aggregate claim amount is given by

$$E(S) = E(N) E(Y) \quad (3)$$

where Y is a generic single claim amount random variable. Clearly, equation (3) is intuitively very reasonable, and the analogous result for the variance is

$$\text{Var}(S) = E(N) \text{Var}(Y) + \text{Var}(N) \{E(Y)\}^2 \quad (4)$$

For risk management and other technical purposes (e.g., stop-loss analysis) (see **Credit Risk Models; Optimal Stopping and Dynamic Programming**), it is of interest to evaluate the distribution of S . Again, conditioning on the number of claims, it follows that

$$\bar{G}(x) = \sum_{n=1}^{\infty} p_n \bar{F}^{*n}(x), \quad x \geq 0 \quad (5)$$

where $G(x) = 1 - \bar{G}(x) = \Pr(S \leq x)$, $p_n = \Pr(N = n)$, and $\bar{F}^{*n}(x) = \Pr(\sum_{i=1}^n Y_i > x)$. As an analytic tool, the Laplace–Stieltjes transform (LST) or probability generating function (pgf) is quite useful in this situation. Let

$$P(z) = E(z^N) = \sum_{n=0}^{\infty} p_n z^n \quad (6)$$

be the pgf of N , and the LST of S is given by

$$E(e^{-zS}) = P(E(e^{-zY})) \quad (7)$$

whereas (in the discrete case), the pgf of S is given by

$$E(z^S) = P(E(z^Y)) \quad (8)$$

In general, evaluation of equation (5) is quite complicated, but for some choices of $\{p_0, p_1, \dots\}$ and/or $F(x) = 1 - \bar{F}(x) = 1 - \bar{F}^{*1}(x)$, it may be simplified. If $F(x)$ is the distribution function (df) of a gamma or inverse Gaussian random variable, then $\bar{F}^{*n}(x)$ admits a simple form. In particular, if $F(x) = 1 - e^{-\mu x}$, then $\bar{F}^{*n}(x) = e^{-\mu x} \sum_{j=0}^{n-1} \frac{(\mu x)^j}{j!}$ and equation (5) becomes

$$\bar{G}(x) = e^{-\mu x} \sum_{j=0}^{\infty} \bar{P}_j \frac{(\mu x)^j}{j!}, \quad x \geq 0 \quad (9)$$

with $\bar{P}_j = \sum_{n=j+1}^{\infty} p_n$. In this case $E(e^{-zY}) = \mu/(\mu + z)$ and equation (7) becomes

$$E(e^{-zS}) = P\left(\frac{\mu}{\mu + z}\right) \quad (10)$$

Furthermore, if N has a zero-modified geometric distribution with $p_n = (1 - p_0)(1 - \phi)\phi^{n-1}$ for $n = 1, 2, \dots$, then $\bar{P}_j = (1 - p_0)\phi^j$ and equation (5) becomes $\bar{G}(x) = (1 - p_0)e^{-\mu(1-\phi)x}$. Suppose, more generally, that Y has a mixed Erlang distribution with $F(x) = 1 - e^{-\mu x} \sum_{k=1}^{\infty} q_k \sum_{j=0}^{k-1} (\mu x)^j / j!$ where $\{q_1, q_2, \dots\}$ is a counting measure. This df may approximate any continuous distribution on $(0, \infty)$ arbitrarily accurately (cf. [1, p. 163]), and is very tractable mathematically (e.g., [2]). One main reason for this mathematical tractability is that $E(e^{-zY}) = Q(\mu/(\mu + z))$ where $Q(z) = \sum_{k=1}^{\infty} q_k z^k$, and thus equation (7) becomes $E(e^{-zS}) = C(\mu/(\mu + z))$ with $C(z) = P(Q(z))$, which is of the same form as equation (10) in the exponential claims case, but with $P(z)$ replaced by $C(z) = P(Q(z))$. Conveniently, $C(z)$ is itself of the discrete compound from equation (8).

Another family of distributions for which explicit computational techniques are available in this situation is the class of phase-type distributions (see **Ruin Probabilities: Computational Aspects; Markov Modeling in Reliability**). See Asmussen and Rolski [3] and references therein for details.

For both theoretical and computational reasons, models for $\{p_0, p_1, \dots\}$ are typically chosen to be of parametric form. In this regard the Poisson distribution with $p_n = \lambda^n e^{-\lambda} / n!$ and $P(z) = \exp\{\lambda(z - 1)\}$ is of central importance. This assumption follows from modeling the stochastic process of the number of claims as a Poisson process. In the compound Poisson case, equation (7) becomes

$$E(e^{-zS}) = e^{\lambda\{E(e^{-zY}) - 1\}} \quad (11)$$

implying that the compound Poisson distribution is infinitely divisible (e.g., [4]). It is instructive to note that infinite divisibility, an important concept in probability theory, is also important in claims modeling in connection with business growth [5, p. 108]. Furthermore, the compound Poisson distribution is itself of central importance in the theory of infinite divisibility.

Compound Poisson distributions are closed under convolution. Thus, if S_i has a compound Poisson distribution with Poisson parameter λ_i and claims

size df $F_i(y)$ for $i = 1, 2, \dots, n$, and the S_i are independent, it follows that $S_1 + S_2 + \dots + S_n$ is again compound Poisson with Poisson parameter $\lambda = \lambda_1 + \lambda_2 + \dots + \lambda_n$ and “claim size” df $F(y) = \{\lambda_1 F_1(y) + \lambda_2 F_2(y) + \dots + \lambda_n F_n(y)\} / \lambda$. This closure property is itself the basis for approximation of the individual risk model, as now described.

Let the portfolio consist of n_{ij} individuals insured for amount i where $i \in \{1, 2, \dots, r\}$ with claim probability q_j where $j \in \{1, 2, \dots, m\}$. If $n_{ij} > 0$, then N_{ijk} is the number of claims for the k th of the n_{ij} individuals for $k \in \{1, 2, \dots, n_{ij}\}$. The total claims are thus $S = \sum_{i=1}^r \sum_{j=1}^m \sum_{k=1}^{n_{ij}} i N_{ijk}$ where $\sum_{k=1}^0 = 0$. Let N_{ijk} have pgf $P_j(z) = E(z^{N_{ijk}})$, and assuming independence of the N_{ijk} , it follows that S has pgf

$$E(z^S) = \prod_{i=1}^r \prod_{j=1}^m \{P_j(z^i)\}^{n_{ij}} \quad (12)$$

which holds even when $n_{ij} = 0$. For the individual risk model, $N_{ijk} \sim \text{Bin}(1, q_j)$, so that $P_j(z) = 1 - q_j + q_j z$. The compound Poisson approximation to the individual risk model involves the approximating assumption that N_{ijk} is Poisson distributed with mean $\lambda_j = \lambda_j(q_j)$. Thus, with $P_j(z) \approx e^{\lambda_j(z-1)}$, equation (12) yields

$$E(z^S) \approx \prod_{i=1}^r \prod_{j=1}^m e^{n_{ij}\lambda_j(z^i-1)} = \prod_{i=1}^r e^{\lambda_i(z^i-1)} \quad (13)$$

where $\lambda_i = \sum_{j=1}^m n_{ij}\lambda_j$. In turn,

$$E(z^S) \approx e^{\lambda\{E(z^Y)-1\}} \quad (14)$$

with $\lambda = \sum_{i=1}^r \lambda_i = \sum_{i=1}^r \sum_{j=1}^m n_{ij}\lambda_j$ and

$$\Pr(Y = i) = \frac{\lambda_i}{\lambda} = \frac{\sum_{j=1}^m n_{ij}\lambda_j}{\sum_{k=1}^r \sum_{j=1}^m n_{kj}\lambda_j}, \quad i = 1, 2, \dots, r \quad (15)$$

If the means are matched then $\lambda_j = q_j$, whereas if the probabilities at 0 are matched then $\lambda_j = -\ln(1 - q_j) > q_j$.

The compound Poisson distribution has many attractive properties, and in particular lends itself to

a simple recursive computational formula, commonly referred to as *Panjer's recursion* [6]. Thus, if

$$E(z^S) = e^{\lambda \left\{ \sum_{y=0}^{\infty} f_y z^y - 1 \right\}} \quad (16)$$

where $\{f_0, f_1, \dots\}$ is a counting measure, then the probability mass function of S may be computed recursively from the formula

$$\Pr(S = x) = \frac{\lambda}{x} \sum_{y=1}^x y f_y \Pr(S = x - y),$$

$$x = 1, 2, \dots \quad (17)$$

beginning with $\Pr(S = 0) = e^{-\lambda(1-f_0)}$. If Y has an absolutely continuous distribution, the distribution of S may be approximated arbitrarily accurately using equation (17) after suitably discretizing the distribution of Y (e.g., [5], Chapter 6).

For some applications (e.g., some lines of automobile insurance), the Poisson assumption may be inappropriate as a result of poor fit to count data (often in the right tail of the distribution), and alternatives may be considered. A computationally attractive family of counting distributions is that for which

$$p_n = \left(a + \frac{b}{n}\right) p_{n-1}; \quad n = 2, 3, 4, \dots \quad (18)$$

where a and b are model parameters not depending on n .

Members of this family, introduced by Sundt and Jewell [7], include the Poisson, negative binomial, binomial, logarithmic series, and extended truncated negative binomial with pgf

$$P(z) = \frac{\{1 - \beta(z - 1)\}^{-r} - (1 + \beta)^{-r}}{1 - (1 + \beta)^{-r}} \quad (19)$$

where $\beta > 0$ and $-1 < r < 0$. Since equation (18) does not involve p_0 , zero-modified versions of these distributions also satisfy equation (18). The ability to select p_0 arbitrarily greatly increases the range of applicability of these models to situations involving various shapes of distributions. See Johnson *et al.* [8] for further discussion of these discrete distributions. Also, from equation (19), $\lim_{\beta \rightarrow \infty} P(z) = 1 - (1 - z)^{-r}$, which is the pgf of the Sibuya distribution, and no distributions satisfy equation (18) other than zero-modified version of those mentioned in this paragraph [9]. See also Hess *et al.* [10].

If equation (18) holds and $E(z^S) = \sum_{n=0}^{\infty} p_n \left(\sum_{y=0}^{\infty} f_y z^y\right)^n$, then equation (17) generalizes for $x = 1, 2, \dots$, to the recursive formula

$$\Pr(S = x) = \frac{\{p_1 - (a + b)p_0\} f_x + \sum_{y=1}^x \left(a + b \frac{y}{x}\right) f_y \Pr(S = x - y)}{1 - a f_0} \quad (20)$$

beginning with $\Pr(S = 0) = P(f_0) = \sum_{n=0}^{\infty} p_n f_0^n$. For further details on the recursive technique, see Sundt [11].

Another extremely important family of distributions in claim count modeling is the family of mixed Poisson distributions with

$$p_n = \int_0^{\infty} \frac{\lambda^n e^{-\lambda}}{n!} dB(\lambda); \quad n = 0, 1, 2, \dots \quad (21)$$

where $B(\lambda)$ is a df on $(0, \infty)$. The pgf associated with equation (21) is

$$P(z) = \int_0^{\infty} e^{\lambda(z-1)} dB(\lambda) = \tilde{b}(1 - z) \quad (22)$$

where $\tilde{b}(s) = \int_0^{\infty} e^{-s\lambda} dB(\lambda)$ is the LST associated with $B(\lambda)$. This importance is a result of both theoretical and practical considerations. From a theoretical viewpoint, heterogeneity in the Poisson claim rate in the portfolio of risks as described by the “structural” df $B(\lambda)$ has much appeal, and mixed Poisson distributions both fit well to many types of claims data and are computationally tractable. What is of central importance in this family is the negative binomial distribution with $B(\lambda)$ as a gamma df, but the Poisson-inverse Gaussian distribution with $B(\lambda)$ as an inverse Gaussian df is a convenient, heavily skewed alternative for which recursive techniques are applicable. More generally, Sichel’s distribution results when $B(\lambda)$ is a generalized inverse Gaussian df. See Grandell [12] for a thorough discussion of mixed Poisson distributions and processes.

Many other parametric models for N have been proposed and are discussed by Johnson *et al.* [8]. The use of recursive techniques with parametric claim count and claim size models as a method for handling deductibles and policy maximums may be found in

Klugman *et al.* [5]. A more advanced discussion is given by Rolski *et al.* [13].

There are various other approaches to evaluation of the total claims distribution (*see Enterprise Risk Management (ERM); Equity-Linked Life Insurance; Nonlife Loss Reserving*), numerical inversion of the LST equation (7), the fast Fourier transform in the discrete case (8), and simulation have also been used in various situations. For larger portfolios, parametric approximations such as the normal distribution based on central limit theoretic arguments may also be used, but the normal distribution itself typically understates the right tail of the aggregate distribution (*see Risk Measures and Economic Capital for (Re)insurers; Simulation in Risk Management; Extreme Value Theory in Finance*). Others include gamma, shifted or translated gamma, Haldane, Wilson–Hilfarty, normal power, and Esscher approximations. See Pentikainen [14] and references therein for further discussion of these methods.

There are also asymptotic formulas available for the extreme right tail, which are well suited for use in conjunction with recursive techniques. In the following text, the notation $a(x) \sim b(x)$, $x \rightarrow \infty$, is used to denote that $\lim_{x \rightarrow \infty} a(x)/b(x) = 1$. First, we assume that

$$p_n \sim Cn^\alpha \theta^n, \quad n \rightarrow \infty \quad (23)$$

where $C > 0$, $-\infty < \alpha < \infty$, and $0 < \theta < 1$. Embrechts *et al.* [15] showed that if there exists $\kappa > 0$ satisfying $E(e^{\kappa Y}) = 1/\theta$ and the distribution of Y is not arithmetic, then

$$\bar{G}(x) \sim \frac{Cx^\alpha e^{-\kappa x}}{\kappa \{\theta E(Ye^{\kappa Y})\}^{\alpha+1}}, \quad x \rightarrow \infty \quad (24)$$

In fact, C may be replaced by a function that varies slowly at infinity. The estimate (24) is often relatively accurate even for small x . A similar result holds if Y has a counting distribution.

An alternative formula to equation (24) often holds in cases where Y has no moment generating function and hence no $\kappa > 0$ may be found. If F is a subexponential df (examples include the Pareto types with regularly varying tails and the lognormal) and the pgf (6) has radius of convergence exceeding 1, then

$$\bar{G}(x) \sim E(N)\bar{F}(x), \quad x \rightarrow \infty \quad (25)$$

The resulting equation (25) is classical and is given by Embrechts *et al.* [16, p. 580], for example. Unfortunately, it is of limited practical use because typically both sides of equation (25) are extremely close to 0 before it becomes accurate. A related asymptotic formula holds when Y has a distribution from a class that includes the (generalized) inverse Gaussian distribution (e.g., [17], and references therein).

Lundberg-type bounds, which often complement the asymptotic formulas, are discussed by Rolski *et al.* [13, Section 4.5] and Willmot and Lin [18, Chapters 4–6].

Finally, we remark that the iid assumption typically made with respect to the claim size sequence $\{Y_1, Y_2, \dots\}$ may sometimes be relaxed. For example, Denuit *et al.* [19] and references therein, consider dependency. Also, the identically distributed assumption may be relaxed with little additional complexity in the case with mixed Poisson claims, a useful approach when incorporating inflation into the model (e.g., [18, Section 4.1]).

Combining Information

Introduction: Meta-Analysis

An area of growing importance in risk assessment involves the combination of information from diverse sources relating to a similar end point. A common rubric for combining the results of independent studies is to apply a *meta-analysis*. The term suggests a move to incorporate and *synthesize* information from many associated sources; it was first coined by Glass [1] in an application of combining results across multiple social science studies. Within the risk analytic paradigm, the possible goals of a meta-analysis include consolidation of results from independent studies, improved analytic sensitivity to detect the presence of adverse effects, and construction of valid inferences on the phenomenon of interest based on the combined data. The result is often a pooled estimate of the overall effect. For example, it is increasingly difficult for a single, large, well-designed ecological or toxicological study to definitively assess the risk(s) of exposure to some chemical hazard (*see Ecological Risk Assessment*). Rather, many small studies may be carried out from which quantitative strategies that can synthesize the independent information into a single, well-understood inference will be of great value. To do so, one must generally assume that the different studies are considering equivalent endpoints, and that data derived from them will provide *exchangeable* information when consolidated. Formally, the following assumptions should be satisfied:

1. All studies/investigations meet basic scientific standards of quality (proper data reporting/collecting, random sampling, avoidance of bias, appropriate ethical considerations, fulfilling quality assurance (QA) or quality control (QC) guidelines, etc.).
2. All studies provide results on the same quantitative outcome.
3. All studies operate under (essentially) the same conditions.
4. The underlying effect is a fixed effect; i.e., it is nonstochastic and *homogeneous* across all studies. (This assumption relates to the exchangeability feature mentioned above.)

In practice, violations of some of these assumptions may be overcome by modifying the statistical model; e.g., differences in sampling protocols among different studies – violating assumption 3 – may be incorporated *via* some form of weighting to de-emphasize the contribution of lower-quality studies.

We also make the implicit assumption that results from all relevant studies in the scientific literature are available and accessible for the meta-analysis. Failure to meet this assumption is often called the *file drawer problem* [2]; it is a form of *publication bias* [3, 4] and if present, can undesirably affect the analysis. Efforts to find solutions to this issue represent a continuing challenge in modern quantitative science [5–7].

Combining P Values

Perhaps the most well-known and simplest approach to combining information collects together P values from $K \geq 1$ individual, independent studies of the same null hypothesis, H_0 , and aggregates the associated statistical inferences into a single, combined P value. Fisher gave a basic meta-analytic technique toward this end; a readable exposition is given in [8]. Suppose we observe the P values $P_k, k = 1, \dots, K$. Under H_0 , each P value is distributed as independently uniform on the unit interval, and using this Fisher showed that the transformed quantities $-2 \log(P_k)$ are each distributed as $\chi^2(2)$. Since their sum is then $\chi^2(2K)$, one can combine the independent P values together into an aggregate statistic: $X_{\text{calcd}}^2 = -2 \sum_{k=1}^K \log(P_k)$. The resulting combined P value is then $P_+ = P[\chi^2(2K) \geq X_{\text{calcd}}^2]$. Report combined significance if P_+ is less than some predetermined significance level, α . This approach often is called the *inverse χ^2 method*, since it inverts the P values to construct the combined test statistic.

One can construct alternative methods for combining P values; for instance, from a set of independent P values, $P_1, P_2, \dots, P_K$, each testing the same H_0 , the quantities $\Phi^{-1}(P_k)$ can be shown to be distributed as standard normal: $\Phi^{-1}(P_k) \sim \text{i.i.d. } N(0, 1)$, where $\Phi^{-1}(\bullet)$ is the inverse of the standard normal cumulative distribution function. We then sum the individual terms to find $\sum_{k=1}^K \Phi^{-1}(P_k) \sim N(0, K)$. Dividing by the corresponding standard deviation, $\sqrt{K}$, yields yet another standard normal random variable. Thus, the

quantity

$$Z_{\text{calcd}} = \frac{1}{\sqrt{K}} \sum_{k=1}^K \Phi^{-1}(P_k) \quad (1)$$

can be used to make combined inferences on H_0 . Owing to Stouffer *et al.* [9], this is known as the *inverse normal method*, or also *Stouffer's method*. To combine the P values into a single aggregate, calculate from Z_{calcd} the lower tail quantity $P_+ = \Pr[Z \leq Z_{\text{calcd}}]$, where $Z \sim N(0,1)$. Notice that this is simply $P_+ = \Phi(Z_{\text{calcd}})$. As with the inverse χ^2 method, report combined significance if P_+ is less than a predetermined α .

Historically, the first successful approach to combining P values involved neither of these two methods. Instead, it employed the ordered P values, denoted as $P_{[1]} \leq P_{[2]} \leq \dots \leq P_{[K]}$. Originally proposed by Tippett [10], the method took the smallest P value, $P_{[1]}$, and rejected H_0 if $P_{[1]} < 1 - (1 - \alpha)^{1/K}$. Wilkinson [11] extended Tippett's method by using the L th ordered P value: reject H_0 from the combined data if $P_{[L]} < C_{\alpha,K,L}$, where $C_{\alpha,K,L}$ is a critical point found using specialized tables [12]. Wilkinson's extension is more resilient to possible outlying effects than Tippett's method, since it does not rest on the single lowest P value. On the other hand, since it relies upon specialized tables it is also far less useful than the other methods discussed above.

Fisher's observation that a P value under H_0 is uniformly distributed can motivate a variety of statistical manipulations to combine independent P values. The few described above represent only the more traditional approaches. For a discussion of some others, see Hedges and Olkin [12].

Effect Size Estimation

While useful and simple, combined P values have drawbacks. By their very nature, P values are summary measures that may overlook or fail to emphasize relevant differences among the various independent studies [13]. To compensate for potential loss of information, one can directly calculate the size of the effect detected by a significant P value. For simplicity, suppose we have a simple two-group experiment where the effect of an external hazardous stimulus is to be compared with an appropriate control group. For data recorded on a continuous scale, the simplest

way to index the effect of the stimulus is to take the difference in observed mean responses between the two groups. When combining information over two such independent studies, it is common to standardize the difference in means by scaling inversely to its standard deviation. Championed by Cohen [14], this is known as a *standardized mean difference*, which for use in meta-analysis is often called an *effect size* [15].

Formally, consider a series of independent two-sample studies. Model each observation Y_{ijk} as the sum of an unknown group mean μ_i and an experimental error term ε_{ijk} : $Y_{ijk} = \mu_i + \varepsilon_{ijk}$, where $i = C$ (control group), T (target group); $j = 1, \dots, J$ studies, and $k = 1, \dots, N_{ij}$ replicates per study. (The indexing can be extended to include a stratification variable, if present; see [16].) We assume that the additive error terms are independently normally distributed, each with mean zero, and with standard deviations, $\sigma_j > 0$, that may vary across studies but remain constant between the two groups in a particular study. Under this model, each effect size is measured *via* the standardized mean difference

$$d_j = \frac{\varphi_j(\bar{Y}_{Tj} - \bar{Y}_{Cj})}{s_j} \quad (2)$$

where $\bar{Y}_{ij}$ is the sample mean of the N_{ij} observations in the j th study ($i = C, T$), s_j is the pooled standard deviation

$$s_j = \sqrt{\frac{(N_{Tj} - 1)s_{Tj}^2 + (N_{Cj} - 1)s_{Cj}^2}{N_{Tj} + N_{Cj} - 2}} \quad (3)$$

using the corresponding per-study sample standard deviations s_{ij} , and φ_j is an adjustment factor to correct for bias in small samples:

$$\varphi_j = 1 - \frac{3}{4(N_{Tj} + N_{Cj} - 2) - 1} \quad (4)$$

We combine the individual effect sizes in equation (2) over the J independent studies by weighting each effect size inversely to its estimated variance, $\text{Var}[d_j]$: the weights are $w_j = 1/\text{Var}[d_j]$. A large-sample approximation for these variances that operates well when the samples sizes, N_{ij} , are roughly equal and are at least 10 for all i and j is [12]

$$\text{Var}[d_j] \approx \frac{N_{Tj} + N_{Cj}}{N_{Tj}N_{Cj}} + \frac{d_j^2}{2(N_{Tj} + N_{Cj})} \quad (5)$$

With these, the weighted averages are

$$\bar{d}_+ = \frac{\sum_{j=1}^J w_j d_j}{\sum_{j=1}^J w_j} \quad (6)$$

Standard practice views a combined effect size as minimal (or “none”) if in absolute value it is near zero, as “small” if it is near $d = 0.2$, as “medium” if it is near $d = 0.5$, as “large” if it is near $d = 0.8$, and as “very large” if it exceeds 1. To assess this statistically, we find the standard error of $\bar{d}_+$ as $se[\bar{d}_+] = 1/\sqrt{\sum_{j=1}^J w_j}$, and build a $1 - \alpha$ confidence interval on the true effect size. Simplest is the large-sample “Wald” interval $\bar{d}_+ \pm z_{\alpha/2} se[\bar{d}_+]$, with critical point $z_{\alpha/2} = \Phi^{-1}(1 - \frac{\alpha}{2})$.

Example: Manganese Toxicity

In a study of pollution risk, Ashraf and Jaffar [17] reported on metal concentrations in the scalp hair of males exposed to industrial plant emissions in Pakistan. For purposes of comparison and control, hair concentrations were also determined from an unexposed urban population ($i = C$). Of interest was whether exposed individuals ($i = T$) exhibited increased metal concentrations in their scalp hair, and if so, how this can be quantified *via* effect size calculations. The study was conducted for a variety of pollutants; for simplicity, we consider a single outcome: manganese concentration in scalp hair. Among six ostensibly homogenous male cohorts (the “studies”), the sample sizes, observed mean concentrations, and sample variances were found as given in Table 1.

(Note that the sample sizes are all large enough with these data to validate use of the large-sample approximation for $\bar{d}_+$.) The per-cohort effect sizes, d_j , based on these data can be computed as $d_1 = 0.558$, $d_2 = 0.785$, $d_3 = 0.763$, $d_4 = 0.544$, $d_5 = 1.080$, and $d_6 = 0.625$. That is, for all cohorts the exposure effect leads to increased manganese concentrations in the T group relative to the C group (since all d_j ’s are positive), ranging from an increase of 0.558 standard deviations for cohort 1 to an increase of over one standard deviation for cohort 5. To determine a combined effect size, we calculate the inverse-variance weights as $w_1 = 8.154$, $w_2 = 7.133$, $w_3 = 10.482$, $w_4 = 10.595$, $w_5 = 7.082$, and $w_6 = 8.581$. From these values, one finds using equation (6) that

$$\begin{aligned} \bar{d}_+ &= \frac{(8.154)(0.588) + \cdots + (8.581)(0.625)}{8.154 + \cdots + 8.581} \\ &= 0.710 \end{aligned} \quad (7)$$

For a 95% confidence interval, calculate

$$se^2[\bar{d}_+] = \frac{1}{8.154 + \cdots + 8.581} = 0.019 \quad (8)$$

with which we find $\bar{d}_+ \pm z_{0.025} se[\bar{d}_+] = 0.71 \pm (1.96)\sqrt{0.019} = 0.71 \pm 0.27$. Overall, a “medium-to-large” combined effect size is indicated with these data: on average, an exposed male has manganese concentrations in scalp hair between 0.44 and 0.98, standard deviations larger than an unexposed male.

Assessing Homogeneity

One can also assess homogeneity across studies, using the statistic $Q_{\text{calcd}} = \sum_{j=1}^J w_j (d_j - \bar{d}_+)^2$ [18], where as above, $w_j = 1/\text{Var}[d_j]$. Under the

Table 1 Sample sizes, sample means, and sample variances for manganese toxicity data, where outcomes were measured as manganese concentration in scalp hair

Cohort, j	1	2	3	4	5	6
<i>i</i> = C (controls)						
N_{Cj}	18	17	22	19	12	18
$\bar{Y}_{Cj}$	3.50	3.70	4.50	4.00	5.56	4.85
s_{Cj}^2	2.43	14.06	4.41	12.25	9.99	4.54
<i>i</i> = T (exposed)						
N_{Tj}	16	14	23	26	24	18
$\bar{Y}_{Tj}$	4.63	6.66	6.46	5.82	9.95	6.30
s_{Tj}^2	5.57	12.74	8.24	9.73	18.58	5.76

null hypothesis of homogeneity across all studies, $Q_{\text{calcd}} \sim \chi^2(J-1)$. Here again, this is a large-sample approximation that operates well when the samples sizes, N_{ij} , are all roughly equal and are at least 10. For smaller sample sizes the test can lose sensitivity to detect departures from homogeneity, and caution is advised.

Reject homogeneity across studies if the P value $P[\chi^2(J-1) \geq Q_{\text{calcd}}]$ is smaller than some predetermined significance level, α . If study homogeneity is rejected, combination of the effects sizes *via* equation (6) is contraindicated since the d_j 's may no longer estimate a homogeneous quantity. Hardy and Thompson [19] give additional details on use of Q_{calcd} and other tools for assessing homogeneity in a meta-analysis; also see [4].

Applied to the manganese toxicity data in the example above, we find $Q_{\text{calcd}} = \sum_{j=1}^6 w_j (d_j - 0.71)^2 = \dots = 1.58$. The corresponding P value for testing the null hypothesis of homogeneity among cohorts is $P[\chi^2(5) \geq 1.58] = 0.90$, and we conclude that no significant heterogeneity exists for this endpoint among the different cohorts. The calculation and reporting of a combined effect size here is validated.

Informative Weighting

Taken broadly, an “effect size” in an environmental study can be any valid quantification of the effect, change, or impact under study [15], not just the difference in sample means employed above. Thus, e.g., we might use estimated coefficients from a regression analysis, potency estimators from a cancer bioassay, correlation coefficients, etc. For any such measure of effect, the approach used in equation (6) corresponds to a more general, weighted averaging strategy to produce a combined estimator. Equation (6) uses “informative” weights based on inverse variances. Generalizing this approach, suppose an effect of interest is measured by some unknown parameter ξ , with estimators $\hat{\xi}_k$ found from a series of independent, homogeneous studies, $k = 1, \dots, K$. Assume that a set of weights, w_k , can be derived such that larger values of w_k indicate greater information/value/assurance in the quality of $\hat{\xi}_k$. A combined

estimator of ξ is then

$$\bar{\xi} = \frac{\sum_{k=1}^K w_k \hat{\xi}_k}{\sum_{k=1}^K w_k} \quad (9)$$

with standard error $se[\bar{\xi}] = 1/\sqrt{\sum_{k=1}^K w_k}$. If the $\hat{\xi}_k$'s are distributed as approximately normal, then an approximate $1 - \alpha$ “Wald” interval on the common value of ξ is $\bar{\xi} \pm z_{\alpha/2} se[\bar{\xi}]$. Indeed, even if the $\hat{\xi}_k$'s are not close to normal, for large K the averaging effect in equation (9) may still imbue approximate normality to $\bar{\xi}$, and hence the Wald interval may still be approximately valid. For cases where approximate normality is difficult to achieve, use of bootstrap resampling methods can be useful in constructing confidence limits on $\bar{\xi}$ [20].

A common relationship often employed in these settings relates the “information” in a statistical quantity inversely to the variance [21]. Thus, given values for the variances, $\text{Var}[\hat{\xi}_k]$, of the individual estimators in equation (9), an “informative” choice for the weights is the reciprocal (“inverse”) variances: $w_k = 1/\text{Var}[\hat{\xi}_k]$. This corresponds to the approach we applied in equation (6). More generally, inverse-variance weighting is a popular technique for combining independent, homogeneous information into a single summary measure. It was described in early reports by Birge [22] and Cochran [18], and Gaver *et al.* [13] give a concise overview.

Combining Information across Models *versus* across studies

Another area where the effort to combine information is important in quantitative risk analysis occurs when information is combined across models for a given study, rather than across studies for a given model. That is, we wish to describe an underlying phenomenon observed in a single set of data by combining the results of competing models for the phenomenon. Here again, a type of informative weighting finds popular application. Suppose we have a set of K models, $M_1, \dots, M_K$, each of which provides information on a specific, unknown parameter θ . Given only a single available data set, we can calculate for θ a point estimator, such as

the maximum-likelihood estimator (MLE) $\hat{\theta}_k$, based on fitting the k th model. Then, by defining weights, w_k , that describe the information in or quality of model M_k 's contribution for estimating θ , we can employ the weighted estimator $\bar{\theta} = \sum_{k=1}^K w_k \hat{\theta}_k$. For the weights, Buckland *et al.* [23] suggest

$$w_k = \frac{\exp(-I_k/2)}{\sum_{i=1}^K \exp(-I_i/2)} \quad (10)$$

where I_k is an information criterion (IC) measure that gauges the amount of information each model provides for estimating θ . Most typical is the general form $I_k = -2\log(L_k) + q_k$, where L_k is the value of the statistical likelihood evaluated under model M_k at that model's MLE, and q_k is an adjustment term that accounts for differential parameterizations across models. This latter quantity is chosen prior to sampling; if we set q_k equal to twice the number of parameters in model M_k , I_k will correspond to the popular Akaike information criterion (AIC) [24]. Alternatively, if we set q_k equal to the number of parameters in model M_k times the natural log of the sample size, I_k will correspond to Schwarz' Bayesian information criterion (BIC) [25]. Other information-based choices for I_k and hence w_k are also possible [26].

Notice that the definition for w_k in equation (10) automatically forces $\sum w_k = 1$, which is not an unusual restriction. Since differences in ICs are typically meaningful, some authors replace I_k in equation (10) with the differences $I_k - \min_{k=1, \dots, K} \{I_k\}$. Of course, this produces the same set of weights once normalized to sum to 1.

Uses of this sort of weighted *model averaging* in risk analytic applications has only recently developed; examples include the use of AIC-based weights by Kang *et al.* to average risk or dose estimates across different microbiological dose-response models [27], Morales *et al.*'s model-averaged benchmark dose estimates for arsenic exposures leading to lung cancer [28], and a study by Wheeler and Bailer [29] comparing model averaging *versus* other model selection options for benchmark dose estimation with quantal data.

Common Cause Failure Modeling

Common cause failures (CCFs) are generally defined as simultaneous failures of multiple components due to a common cause. “Simultaneity” can be perfect or a time frame such that the failed states (downtimes, unavailabilities) of multiple components overlap. Failure causes can originate from design, manufacturing or installation weaknesses that are common to many components or from environmental stresses (impact, vibration, grit, heat, etc.), common maintenance weaknesses or human errors in operation. A cause can be external to the components, or it can be a single failure that propagates to other components in a cascade (like a pipe whip or a turbine missile). Even if such events are rare compared to single failures of a component, they can dominate system unreliability or unavailability. For example, consider a system of four parallel similar trains of components with the same unavailability $p = 0.02$. Without CCF the system unavailability is calculated as $P_0 = p^4 = 1.60 \times 10^{-7}$. Assume that a small fraction $\beta = 0.03$ of component unavailabilities are due to causes that fail all four components, causing the system to fail. Then the single failure unavailability is $(1 - \beta)p$, and the system unavailability $P_c = \beta p + (1 - \beta p)[(1 - \beta)p]^4 = 6.00 \times 10^{-4}$. The result is dominated by CCF.

Before quantified event data was available on CCF a bounding method was used, assuming the system failure probability to be a geometric mean of two bounds. The lower bound is the one that would exist if there were no CCF and all probabilities are treated as independent. The upper bound equals the largest single subsystem failure probability. In the example, this yields system probability $P = \sqrt{p \cdot p^4} = 5.66E-5$. Later on, several parametric models, like the β -factor model above, were developed under the assumption and hope that such parameters would be globally generic constants that everybody could use without having to estimate them for each plant or system separately. After many more CCF events have been observed it has become evident that also the ratio parameters like β depend on component types and failure modes,

and vary from system to system even for similar components.

In probabilistic safety assessments (PSAs) CCF can have major impacts in two ways:

- in *production systems* they can cause initiating events and demand safety systems to start and operate, and
- in *safety systems* they fail multiple components, usually similar components in redundant subsystems (trains).

In normally operating systems, a CCF occurs at a random time owing to *time-related stresses*, and a proper model is based on general multiple-failure rates (GMFR) $\lambda_{a,b,\dots}$ such that $\lambda_{a,b,\dots} dt$ is the probability of an event failing the specific components $a, b, \dots$ in a small time interval dt .

In standby safety systems, failures can be caused by two kinds of stresses. *Demand-related stresses* cause components $a, b, \dots$ to fail with a certain general multiple-failure probability (GMFP) $q_{a,b,\dots}$ per system demand, at the time of an initiator or in a periodic test. Demand-related stresses cause degradation due to cold-start-up wear, crack propagation, and thermal transients or loosening etc. due to start-up shocks. Failures can also occur owing to *time-related stresses* at random times (due to corrosion, thermal aging, creep, embrittlement, externally caused vibration and fatigue, random external loads or chemical attacks, dust, dirt, or dry-out). These are properly modeled by a probability per unit time, i.e., by standby failure rates $\lambda_{a,b,\dots}$. Usually, these failures remain unrevealed until discovered by a scheduled test. Test demands of a component are carried out at certain times, usually with regular time intervals T . If a failure is discovered in a test, the component is immediately repaired. These two categories of CCF are addressed here:

- failures caused by demand (start-up) stresses and
- failures caused by time-related stresses.

Any group of standby components can be subject to both types of stresses and may have finite values for both $q_{a,b,\dots}$ and $\lambda_{a,b,\dots}$. A reason to handle these separately is that their impact on a system depends differently on test interval T , a quantity that may be varied to control risk.

Explicit Models and Multiple-Failure Parameters

Explicit modeling of multifailure states means that a CCF of components $a, b, c, \dots$ is described in a system model by a basic event $Z_{a,b,c,\dots}$, input to the OR gate of each component $a, b, c, \dots$, parallel to the individual single failure events $Z_a, Z_b, Z_c, \dots$, indicated by the subindexes. This is illustrated by Figure 1. The components being subject to a set of common causes are called a *common cause component group* (CCCG), usually n similar components in n parallel trains (subsystems) of a safety system, and n is called the size of the group.

Common cause failures that occur owing to the stresses caused by a true system demand (an initiating event) or a system test demand (simultaneous or consecutive testing of all n components of a CCCG) are usually modeled by constant probabilities $z_{a,b,c,\dots} \equiv P(Z_{a,b,c,\dots}) = q_{a,b,c,\dots}$, which is the fraction of system demands that fail $a, b, \dots$. For another interpretation, consider initiating events occurring evenly at any time during a test interval. Then, $q_{a,b,c,\dots}$ is the probability that the preceding system test has damaged or weakened components $a, b, \dots$ so that they can not perform if a true demand occurs before the next test cycle. The time window of vulnerability for this CCF is the interval T , because at the next test the damage would be discovered and repaired. The fraction of vulnerable intervals is the basic event probability $z_{a,b,c,\dots} = q_{a,b,c,\dots}$.

Often, subsets of components of a CCCG are assumed to be identically subject to common

causes so that all combinations of the same multiplicity have the same probability. This *symmetry assumption* allows definitions $q_{1/n} \equiv q_a = q_b = \dots$, $q_{2/n} \equiv q_{a,b} = q_{a,c} = q_{b,c} = \dots$, $q_{3/n} \equiv q_{a,b,c} = q_{a,c,d} \dots$, etc. With simultaneous testing, the basic event probabilities are $z_{k/n} = q_{k/n}$. The total probability of a k/n event (CCF of k components out of n) in a system demand is $Q_{k/n} = n!/(k!(n-k)!)q_{k/n}$.

An alternative scheme to test n components is *evenly staggered* testing, in which case there is a time shift T/n between successive tests of components. Assume that there is a rule to do extra testing of all other components when one is found to demand repair, so called extra-testing rule (ETR). The effect of staggered testing and ETR is that a CCF is discovered and repaired sooner than with simultaneous testing. Because the test cycle length of any specific subset of k components is T , the mean time between consecutive tests of these components is T/k . Thus, a test-caused CCF of any k components is discovered and repaired within T/k in the average. This is the average downtime for a specific CCF ($Z_{k/n}$) in fraction $q_{k/n}$ of the cycles. Summarizing for demand-caused CCF the basic event probabilities (slightly idealized) are

$$z_{k/n} = q_{k/n} \quad (1)$$

with simultaneous or consecutive testing

$$z_{k/n} = \frac{q_{k/n}}{k} \quad (2)$$

with staggered testing and ETR.

In both cases one may add the repair time contribution $q_{k/n}\tau_{k/n}/T$, where $\tau_{k/n}$ is the downtime of a

Figure 1 Developing a component-event fault tree to a cause-event fault tree

group of k components due to repair of CCF. This does not depend on the testing scheme.

On the other hand, time-related stresses cause time-dependent unavailabilities between tests. $P(Z_{a,b,\dots}) = \lambda_{a,b,\dots}(t - T_i)$ is the probability of failed states of components $a, b, \dots$ at time t due to a common cause failing exactly these components simultaneously with rate $\lambda_{a,b,\dots}$ when the last possible discovery and repair of such failure occurred at T_i . The time factors are usually small so that the linear approximation is valid. The symmetry assumption reduces the number of rates because then $\lambda_{1/n} \equiv \lambda_a = \lambda_b = \dots, \lambda_{2/n} \equiv \lambda_{a,b} = \lambda_{a,c} = \lambda_{b,c} = \dots, \lambda_{3/n} \equiv \lambda_{a,b,c} = \lambda_{a,c,d} \dots$, etc. All together k/n events occur with the total rate $\Lambda_{k/n} = n!/(k!(n-k)!) \lambda_{k/n}$.

Often, the time-average risk is analyzed rather than the risk as a function of time. The basic event probabilities $P(Z_{a,b,\dots})$ that yield the time-average risk (slightly idealized again) are [1]

$$z_{k/n} \approx \frac{1}{2} \lambda_{k/n} T \quad (3)$$

when all trains are tested simultaneously or consecutively

$$z_{k/n} \approx \frac{1}{2k} \lambda_{k/n} T \quad (4)$$

for staggered testing with ETR.

In both cases one may add the repair-time contribution $\lambda_{k/n} \tau_{k/n}$. Without ETR some $z_{k/n}$ are larger than equations (2, 4) indicate.

Other parametric models will be presented in relation to the GMFRs $\lambda_{k/n}$ and GMFPs $q_{k/n}$ because these parameters are easy to estimate and they do not depend on testing schemes or test intervals.

Basic Parametric Models

The early CCF models were developed under the assumption that a few parameters could model and predict CCFs. These models and their common features are now described.

β -Factor model

This model was first introduced for the case $n = 2$ with a ratio parameter, $\beta = (\lambda_{2/2})/(\lambda_{1/2} + \lambda_{2/2})$ [2]. If this is known, one needs to estimate only a single failure rate $\lambda_{1/2}$ for a specific plant and

component type, then obtain $\lambda_{2/2} = \beta/(1 - \beta)\lambda_{1/2}$, and use this in the basic event probability equation for $z_{2/2}$. Numerical values of β have been presented for several types of components [3, 4] in the range 0.01–0.09, with error factors about 2.5. Likewise, β can be defined for demand-caused failures as $q_{2/2}/(q_{1/2} + q_{2/2})$. The model can be generalized for larger CCCG sizes $n > 2$ as was illustrated in the introduction for $n = 4$.

Binomial Failure-Rate Model (BFRM)

The binomial model [5, 6] was also originally based on time-related failures. It makes the symmetry assumption and has four parameters, λ , μ , p , and ω . The independent failure rate of a single component is λ , not counting any faults due to common causes, and ω is the rate of “lethal” shocks that fail all components of a CCCG, independent of the size n . The third rate μ is the rate of nonlethal shocks that can fail any one of the n components with a certain probability (“coupling parameter”) p . The number failed by a nonlethal shock is binomially distributed, and

$$\lambda_{1/1} = \lambda + \mu p + \omega \quad (5)$$

$$\lambda_{1/n} = \lambda + \mu p(1 - p)^{n-1}, n > 1 \quad (6)$$

$$\lambda_{k/n} = \mu p^k (1 - p)^{n-k}, 1 < k < n \quad (7)$$

$$\lambda_{n/n} = \mu p^n + \omega, n > 1 \quad (8)$$

One can conclude that data from a system with $n = 2$ or 3 alone would not be enough to estimate four parameters, but data from systems with $n = 4$ would be just enough. If data is available from both systems with $n = 2$ and 3, then estimated five rates $\lambda_{1/2}$, $\lambda_{2/2}$, $\lambda_{1/3}$, $\lambda_{2/3}$, and $\lambda_{3/3}$ would be more than enough to solve four parameters. In general, some fitting is needed when the number of observable rates is larger than four. Numerical parameters for several types of components have been published [7].

One can define the binomial model for demand-caused failures as well. Then, λ , μ , and ω are redefined as probabilities per system demand rather than per unit time, and equations (5–8) are for the probabilities $q_{k/n}$. Another model with four parameters is a recently introduced process-oriented simulation (POS) model [8].

Stochastic Reliability Analysis Model (SRAM)

The stochastic reliability analysis model (SRAM) assumes a random probability P with a probability density $g(p)$ so that specific k out of n components fail with probability per demand $q_{k/n} = \int_0^1 g(p) p^k (1-p)^{n-k} dp$ [9]. This can also be applied to time-related failures by defining a general rate parameter Λ so that $\lambda_{k/n} = \Lambda q_{k/n}$. A model similar to binomial failure-rate model (BFRM) can be obtained by defining $g(p)$ as a set of Dirac's δ functions. A single beta distribution for $g(p)$ has been defined as a random probability shock model [10]. A more general distributed failure probability model (DFPM) with $g(p) = \sum_j C_j f_j(p)$ has also been suggested, where C_j is the fraction of time "environment j " is present. The coefficients C_j and the densities $f_j(p)$ are empirically determined β densities associated with failure multiplicities j [11]. A model in this category is also the coupling model [12].

Common Load Model

The common load model (CLM) assumes all n components of a CCCG to be subject to a common load X having a cumulative distribution $S(x)$, and each component has a strength Y with a cumulative distribution $F(y)$. Any specific k components then fail with probability $q_{k/n} = \int_{-\infty}^{\infty} F^k(x) [1 - F(x)]^{n-k} dS(x)$ for any k and n [13]. This model can be extended to time-related causes by defining a common rate Λ so that $\lambda_{k/n} = \Lambda q_{k/n}$. The distributions $S(x)$ and $F(x)$ need to be fitted by calibrating the model with relevant empirical data.

Common Features of the Parametric Models

The early parametric models were based on a few essential parameters, some built into the distributions $g(p)$, $F(x)$, and $S(x)$. An important characteristic of each model is the number of free parameters available to determine all basic event probabilities or initiating event rates. It is common to assume that the more parameters in the model, the more flexible it is and potentially more accurate. However, it has been shown that all the models defined so far are constrained by the so-called external cause mapping rule [14]

$$\lambda_{k/n} = \lambda_{k/n+1} + \lambda_{k+1/n+1} \quad (9)$$

and similarly for $q_{k/n}$. This indicates how the rates of systems with different CCCG sizes are coupled under these models. Equation (9) is a constraint because it means that the models have no more than n genuinely free rates associated with all CCCG sizes $n' \leq n$, when in fact the total number of such rates $\lambda_{k'/n'}$ with $k' \leq n' \leq n$ is equal to $n(n+1)/2$. The constraint equation (9) is built also into SRAM and CLM no matter how general and complex distributions are used for $g(p)$, $F(x)$, and $S(x)$. Furthermore, it has been shown that [14]

- for any BFRM and CLM there is an equivalent SRAM, and
- any set of failure rates $\lambda_{k/n}$ satisfying equation (9) can be presented by an SRAM.

Thus, using any of the early parametric models entails inherent adoption of equation (9). Still, there seems to be no physical reason or convincing empirical evidence to prove equation (9) or any other simple mapping rule. This is because systems with different sizes n are often designed by different vendors using different designs, separation, and layout principles. Many plant-specific details and operation and maintenance practices can also mask the impact of n and induce plant-to-plant variations in CCF parameters.

General Ratio Models

Two other parametric CCF models, the alpha-factor model (AFM) [15] and the multiple Greek letter model (MGLM) [16], are based on the ratios of multiple-failure rates or probabilities. These models are general but need at least one rate or probability from outside of the models to determine numerical values for the basic event probabilities.

α -Factor Model (AFM)

This model is based on the following ratios of the basic event rates,

$$\alpha_{k/n} \equiv \frac{\Lambda_{k/n}}{\Lambda_n} \quad (10)$$

where $\Lambda_n \equiv \Lambda_{1/n} + \Lambda_{2/n} + \dots + \Lambda_{n/n}$ is the total event rate. The definition can be made analogously with the demand-related failure probabilities, $\alpha_{k/n} \equiv Q_{k/n}/Q_n$ with $Q_n = Q_{1/n} + \dots + Q_{n/n}$. Obviously,

$\alpha_{1/n} + \alpha_{2/n} + \dots + \alpha_{n/n} = 1$ so that the α s are not mutually independent. If the α 's and at least one of the rates $\Lambda_{k/n}$ or the sum Λ_n are known, all other rates $\Lambda_{k/n}$ and then the basic event probabilities can be solved. For example, $\lambda_{k/n} = \alpha_{k/n} \Lambda_n / \binom{n}{k}$ can be used in equations (3, 4). In this way the model has the same number of free parameters as the total number of rates, and the model is not inherently constrained by equation (9). Nonetheless, an analyst who estimates a plant-specific rate and combines it with global or generic α factors makes a definite assumption about the validity of the average α 's for his target plant.

Multiple Greek Letter Model (MGLM)

In this model the parameters $\beta, \gamma, \delta, \varepsilon, \mu, \dots$ are conditional probabilities defined in terms of the ratios of the partial sums $S_{m,n} = \sum_{k=m}^n k \Lambda_{k/n}$,

$$\begin{aligned} \beta &= \frac{S_{2,n}}{S_{1,n}}, & \gamma &= \frac{S_{3,n}}{S_{2,n}}, \\ \delta &= \frac{S_{4,n}}{S_{3,n}}, & \varepsilon &= \frac{S_{5,n}}{S_{4,n}}, \text{ etc.} \end{aligned} \quad (11)$$

The definitions can be made similarly in terms of the demand failure probabilities $Q_{k/n}$ in place of $\Lambda_{k/n}$. If the Greek letters and one of the sums $S_{m,n}$ is known, all rates can be solved, e.g.,

$$\begin{aligned} \Lambda_{1/n} &= (1 - \beta) S_{1,n}, \\ \Lambda_{2/n} &= \frac{1}{2} \beta (1 - \gamma) S_{1,n}, \\ \Lambda_{3/n} &= \frac{1}{3} \beta \gamma (1 - \delta) S_{1,n}, \text{ etc.} \end{aligned} \quad (12)$$

One approach is to estimate $S_{1,n}$ based on data at a specific plant, and take values of the Greek letters from published generic values for each component type. This entails an assumption of plant-independence of the generic or mean value ratios.

Data and Application Issues

The choice of model depends mainly on answers to the following two questions:

- What kind of data is available for the CCF parameters and observed events?
- What is the intended use of the system reliability or risk model?

One hypothesis made in the past for reaching plant specificity is to assume that one can take generic or average ratio parameters, such as β or α factors, and combine them with plant- or site-specific single failure rates or total failures rates. This hybrid approach is attractive because single-failure data accumulate more rapidly at a single plant or within a family of identical systems. A model based on this approach may be used to assess orders of magnitude risks. But it may need extra care and safety margins if applied to most serious plant-specific operative decisions.

A large collection of α factors and MGL parameters for many types of components and failure modes has been published [17]. It was concluded that CCF parameters depend on component types, and even for similar components they vary among systems and failure modes. For example, β factors are not the same in different systems or for different failure modes of a specific component type. Table 1 shows a sample of mean values and variations of α 's for many types of components and failure modes [18].

If a system model is intended for detailed risk-informed decision making on allowed plant configurations, system modifications, inspections, test intervals, maintenance programs, etc., then the CCF model must have sufficient degrees of freedom and the input parameters should be as plant-specific as possible. This is possible if the plant collects failure data or is part of a failure data collection system, and

Table 1 α -Factor generic mean values and component type variations for $n = 2, 3$, and $4^{(a,b)}$

α factor	$\alpha_{1/2}$	$\alpha_{2/2}$	$\alpha_{1/3}$	$\alpha_{2/3}$	$\alpha_{3/3}$	$\alpha_{1/4}$	$\alpha_{2/4}$	$\alpha_{3/4}$	$\alpha_{4/4}$
Mean value	0.955	0.0454	0.948	0.0281	0.0239	0.944	0.0279	0.0110	0.0173

has access to a large national CCF-event data collection system (such as [19] or [20]) or the multinational project international common-cause data exchange (ICDE) [21]. Plant-specific CCF parameters may then be estimated by combining data from many plants with an empirically based Bayesian framework. This is briefly described for the parameters GMFR and GMFP.

Estimation of Parameters

Estimation of $\lambda_{k/n}(\Lambda_{k/n})$ and $q_{k/n}(Q_{k/n})$ is described because the basic event probabilities and all other parameters can be presented in terms of these GMFR and GMFP.

Estimation Based on Ideal Data

Consider first demand-caused failures at a single plant or system. The k/n events occur with a total probability $Q_{k/n} = n!/(k!(n-k)!)q_{k/n}$ per system demand ($1 \leq k \leq n$). When N_n system demands (cycles of demands of all n components of a CCG) have been made, the number of k/n events, $N_{k/n}$, has a binomial distribution with the probability parameter $Q_{k/n}$. The expected value is $E(N_{k/n}) = Q_{k/n}N_n$. Estimation of $Q_{k/n}$ based on the observed $N_{k/n}$ and N_n yields a probability density for $Q_{k/n}$, a beta distribution with the following mean value and variance:

$$E(Q_{k/n}) = \frac{N_{k/n} + 1/2}{N_n + 1} \quad (13)$$

$$\sigma^2(Q_{k/n}) = \frac{(N_{k/n} + 1/2)(N_n + 1/2 - N_{k/n})}{(N_n + 1)^2(N_n + 2)} \quad (14)$$

These results can be obtained by Bayesian formalism using noninformative priors, and also by classical-confidence bounds.

The procedure with time-caused CCF is analogous. The observable k/n events occur with a total rate $\Lambda_{k/n} = n!/(k!(n-k)!) \lambda_{k/n}$ and the number of k/n events $N_{k/n}$ in observation time T_n has a Poisson distribution with mean value and variance equal to $E(N_{k/n}) = \Lambda_{k/n}T_n$. Estimation yields the probability distribution gamma with the mean value and the

variance

$$E(\Lambda_{k/n}) = \frac{N_{k/n} + 1/2}{T_n} \quad (15)$$

$$\sigma^2(\Lambda_{k/n}) = \frac{N_{k/n} + 1/2}{T_n^2} \quad (16)$$

It matters little for these estimations how the $N_{k/n}$ events were found: in staggered or nonstaggered tests or in some other system demands. After $\lambda_{k/n} = \Lambda_{k/n}/\binom{n}{k}$ and $q_{k/n} = Q_{k/n}/\binom{n}{k}$ have been estimated, they determine the basic event probabilities (1–4) without any need for other models.

Assessment Uncertainties

Due to uncertainties in event observations, interpretations, and documentation, it is not always known with certainty how many components actually were failed at the time of the observation, and were they caused by demands or time-related stresses. Then the numbers $N_{k/n}$ are not known exactly. The effects of this uncertainty can be quantified by assessing the following conditional assessment probabilities for each plant, for each event observed, and for each event multiplicity k/n : $w_{\lambda,i}(k/n)$ [$w_{q,i}(k/n)$] = the probability, conditional on the symptoms and characteristics observed, that observation i entails a k/n -failure event and the failure is caused by time-related (demand-related) stresses; $0 \leq w_{\lambda,i}(w_{q,v}) \leq 1$.

To quantify these assessment probabilities one has to consider the evidence of a coupling mechanism (common cause), the degrees of degradation of each component, and the simultaneity of the failures. A component is considered failed if it needs repair to be able to work in the next test or true demand. A basic framework for the assessment was presented e.g., in [22], and further refinements and options with multiple k/n events and higher moments in [1, 18, 23, 24]. The assessment probabilities can be used to determine the distributions and moments of $N_{k/n}$, separately for time-related and demand-related causes. The distributions of each $\lambda_{k/n}$ and $q_{k/n}$ are weighted averages of gamma and beta distributions, respectively. The probabilities have the following mean and variance:

$$E(Q_{k/n}) = \frac{\sum_{i=1}^N w_{q,i}(k/n) + 1/2}{N + 1} \quad (17)$$

$$\begin{aligned}
& \sigma^2(Q_{k/n}) \\
&= \frac{\left[\sum_{i=1}^N w_{q,i}(k/n) + 1/2 \right] \times \left[N + 1 - \sum_{i=1}^N w_{q,i}(k/n) - 1/2 \right]}{(N+1)^2(N+2)} \\
&+ \frac{\sum_{i=1}^N w_{q,i}(k/n)[1 - w_{q,i}(k/n)]}{(N+1)(N+2)} \quad (18)
\end{aligned}$$

where N is the total number of observed system demands. Corresponding moments for the time-related rates are

$$E(\Lambda_{k/n}) = \frac{\sum_{i=1}^N w_{\lambda,i}(k/n) + 1/2}{T_n} \quad (19)$$

$$\begin{aligned}
\sigma^2(\Lambda_{k/n}) &= \frac{\sum_{i=1}^N w_{\lambda,i}(k/n) + 1/2}{T_n^2} \\
&+ \frac{\sum_{i=1}^N w_{\lambda,i}(k/n)[1 - w_{\lambda,i}(k/n)]}{T_n^2} \quad (20)
\end{aligned}$$

As an example, consider a hypothetical system of four standby diesel generators. Five observations of CCF events “failure to start” have been made in time $T_4 = 10$ years. The assessment probabilities are listed in Table 2.

Additional 22 single-failure events with $w_{\lambda,i}(1/4) = 1$ are not listed but can be used for estimating $\Lambda_{1/4}$. Equations (19, 20) yield (in units/

year) $E(\Lambda_{1/4}) = 2.25$, $E(\Lambda_{2/4}) = 0.285$, $E(\Lambda_{3/4}) = 0.260$, $E(\Lambda_{4/4}) = 0.105$, $\sigma(\Lambda_{1/4}) = 0.474$, $\sigma(\Lambda_{2/4}) = 0.195$, $\sigma(\Lambda_{3/4}) = 0.192$, $\sigma(\Lambda_{4/4}) = 0.121$. Dividing by the binomial factors this data set yields the mean values and standard deviations

$$\begin{aligned}
E(\lambda_{1/4}) &= 0.563, & \sigma(\lambda_{2/4}) &= 0.119 \\
E(\lambda_{2/4}) &= 0.0475, & \sigma(\lambda_{2/4}) &= 0.0325 \\
E(\lambda_{3/4}) &= 0.0650, & \sigma(\lambda_{3/4}) &= 0.0480 \\
E(\lambda_{4/4}) &= 0.105, & \sigma(\lambda_{4/4}) &= 0.121 \quad (21)
\end{aligned}$$

With staggered testing, ETR, and test interval $T = 4$ weeks the expected basic event probabilities can be obtained from equation (4) as $z_{1/4} = 0.02165$, $z_{2/4} = 0.00091$, $z_{3/4} = 0.00083$, and $z_{4/4} = 0.00101$. With consecutive testing equation (3) yields $z_{1/4} = 0.02165$, $z_{2/4} = 0.00183$, $z_{3/4} = 0.00250$, and $z_{4/4} = 0.00404$.

Extension of the method is available to cases with more than one k/n event (of the same multiplicity) in a single observation [23, 24].

Quantification Using Multiple Data Sources

If event data for a certain type of equipment can be assumed to be from identical systems (e.g., the same n , similar physical separation principles, similar maintenance practices, and similar operating conditions as the system of interest at the target plant), one may pool the observations, the numbers of failures of each multiplicity k/n and observation times (or numbers of system demands) and use the earlier estimation equations for all $\lambda_{k/n}$ and $q_{k/n}$. This highest degree of similarity is rarely the case.

A more realistic approach is to obtain CCF data from a family of systems whose members are not quite identical but are “similar enough” to the system of interest (the target system) in the sense that one can consider each system as a sample from the same family. For example, high-pressure safety injection systems designed by the same vendor with the same CCCG size n and the same layout and separation principles between redundant trains are quite similar, but installation, testing, and maintenance practices may vary between plants causing some variation in CCF frequencies. Assuming such plants to be samples from the same family allows the methodology of

Table 2 Assessment probabilities for diesel generator system $n = 4$ for $k = 2, 3, 4$

Observation i	$w_{\lambda,i}$ (2/4)	$w_{\lambda,i}$ (3/4)	$w_{\lambda,i}$ (4/4)
1	0.90	0.10	0.0
2	0.45	0.50	0.05
3	0.25	0.50	0.25
4	0.50	0.50	0.0
5	0.25	0.50	0.25

empirically based Bayesian methods to be used in estimating CCF rates for each plant of the family, including the plant of interest. This method uses available data to maximal extent without assuming identity, and yields proper values also for plants that have experienced no CCF. Input to this method are the sets $\{(N_{k/n}, T_n)\}$ or $\{(N_{k/n}, N_n)\}$, data pairs for each plant in the family. From these the empirical or hierarchical Bayes methods construct a prior distribution and posterior distributions for all plants, or just for a single target plant.

When assessment uncertainties are present, the numbers $N_{k/n}$ are not exactly known. One approach is to define effective pairs $\{N_{k/n}^*, T_n^*\}$ or $\{N_{k/n}^*, N_n^*\}$ so that equations (13–16) yield exactly the moments (equations 17–20). Then such virtual data input to the Bayesian process yields prior and posterior distributions for the rates and the probabilities consistent with the observations up to the first two moments. The procedure is described in [1] for time-related failures, and the essentials in [25] for demand-related failures. Figure 2 shows the overall procedure (*see Bayesian Statistics in Quantitative Risk Assessment*).

Applications of this procedure for emergency cooling system pumps and diesel generators indicate that the choice of the data base and source plants influences the results, and plant-to-plant variations can be large [1].

As long as CCF data is sparse there is a temptation to adopt event data even from plants with different CCCG sizes n . This requires assumptions about how to judge the applicability of events and modify the rates or assessment weights from larger to smaller systems and *vice versa*. There are alternatives to the mapping equations (9) [1, 24]. These somewhat controversial issues may be better to avoid until there is sufficient empirical evidence to show which rules, if any, are valid between the rates of different group sizes n . So far it seems that only the ratios of the total CCF rates $\eta_{n,n+1} = \lambda_{n+1/n+1}/\lambda_{n/n}$ for $n > 1$ are reasonably common for many types of components. This can be concluded from Table 3.

Other Dependent Failures and Methods

The models described so far apply to safety systems vulnerable to CCF occurring randomly in time or

Figure 2 Common cause failure quantification procedure

^(b)These do not include plant-to-plant variations

due to stresses caused by tests and demands. The generic multifailure rates apply also for initiating events caused by CCF. Other types of dependent events are as follows:

- Design, manufacturing, and installation errors that make multiple components vulnerable to some initiators from the very beginning. Examples include incorrect pipe supports against seismic events, or temporary flow strainers left in emergency cooling pipelines. Explicit modeling by failure probabilities is rather straightforward, but data for parameters is rare.
- CCF initiators are initiating events that simultaneously fail components in safety systems intended to protect against the initiator. These may be modeled as special initiating events.
- Plant-specific dependences may be created if a system has design features different from earlier plants. These can induce special CCF not yet observed in the past experience or CCF data sources. System-specific walkthroughs, interviews and questionnaires can be used to identify and quantify such vulnerabilities.
- Consecutive human actions are generally dependent [26]. Repeated human errors can be treated as CCF events in risk assessments. The basic dependency models available can account for operator actions and periodic testing and maintenance actions [27].

There is also an *implicit* method for incorporating CCF in system analysis. It is based on first solving the system probability expression without CCF, and then modifying the multicomponent terms to account for CCF [28]. Quite general dependencies between components can also be modeled explicitly by defining independent virtual basic events and their probabilities [29].

A challenge to system designers is how to eliminate or minimize CCF contributions to system failures. Many defenses against CCF have been identified, with the degree of redundancy and diversity usually on top of the list [4]. Identification of defenses is also a part of CCF data collection programs [21].

Comonotonicity

Aggregating Nonindependent Risks

In an actuarial or financial context, one often encounters a random variable (r.v.) S of the type

$$S = \sum_{i=1}^n X_i \quad (1)$$

For an insurer the X_i may represent the claims from individual policies over a specified time horizon, while S represents the aggregate risk related to the entire insurance portfolio. In another context, the X_i may denote the risks of a particular business line, and S is then the aggregate risk across all business lines (see **Actuary; Inequalities in Risk Theory; Insurance Applications of Life Tables; Longevity Risk and Life Annuities; Risk Classification/Life**). In the context of a pension fund, r.v.'s of this type appear when determining provisions and related optimal investment strategies. Another field of application concerns personal finance problems where a decision maker faces a series of future consumptions and looks for optimal saving and investment strategies. Random variables of this type are also used to describe the payoffs of Asian and basket options. Finally, they also appear in the context of capital allocation or capital aggregation (see **From Basel II to Solvency II – Risk Management in the Insurance Sector**). All these applications amount to the evaluation of risk measures related to the cumulative distribution function (cdf) $F_S(x) = \Pr[S \leq x]$ of the r.v. S . The interested reader may refer to [1–6], for more details.

Let us denote the random vector $(X_1, X_2, \dots, X_n)$ by $\underline{X}$. To avoid technical complications, we always assume that the expectations of the X_i exist. When the r.v.'s X_i are mutually independent, the cdf of S can be computed using the technique of convolution or by recursive computation methods such as De Pril's recursion and Panjer's recursion, amongst others; see, for example [7–9].

However, in many actuarial and financial applications, the individual risks X_i in the sums S cannot be assumed to be mutually independent for instance, because all the X_i are influenced by the same economic or physical environment. As a consequence, it is not easy to determine the cdf of S .

Comonotonic Random Variables

Let us consider the situation where the individual risks X_i of the random vector $\underline{X}$ are subject to the same claim generating mechanism such that

$$\underline{X} \stackrel{d}{=} (g_1(Z), g_2(Z), \dots, g_n(Z)) \quad (2)$$

for some r.v. Z and nondecreasing functions g_i . Here, “ $\stackrel{d}{=}$ ” stands for “equality in distribution”. In this case, the random vector $\underline{X}$ is said to be “comonotonic” and the distribution of $\underline{X}$ is called the *comonotonic distribution* (see **Premium Calculation and Insurance Pricing**).

One can prove that the comonotonicity of $\underline{X}$ can also be characterized by

$$\underline{X} \stackrel{d}{=} (F_{X_1}^{-1}(U), F_{X_2}^{-1}(U), \dots, F_{X_n}^{-1}(U)) \quad (3)$$

where $F_{X_i}^{-1}$ denotes the quantile function of the r.v. X_i , and U is a uniformly distributed r.v. on the unit interval. It is easy to prove that comonotonicity of $\underline{X}$ is also equivalent to

$$F_{\underline{X}}(\underline{x}) = \min[F_{X_1}(x_1), F_{X_2}(x_2), \dots, F_{X_n}(x_n)] \quad (4)$$

Hoeffding [10] and Fréchet [11] have shown that the function $\min[F_{X_1}(x_1), F_{X_2}(x_2), \dots, F_{X_n}(x_n)]$ is the cdf of a random vector which has the same marginal distributions as the random vector $\underline{X}$.

Let us denote the sum of the components of the comonotonic random vector $(F_{X_1}^{-1}(U), F_{X_2}^{-1}(U), \dots, F_{X_n}^{-1}(U))$ by S^c :

$$S^c = \sum_{i=1}^n F_{X_i}^{-1}(U) \quad (5)$$

Several important actuarial quantities of S^c , such as quantiles and stop-loss premiums, exhibit an additivity property in the sense that they can be expressed as a sum of corresponding quantities of the marginals involved. For the quantiles, we have that

$$F_{S^c}^{-1}(p) = \sum_{i=1}^n F_{X_i}^{-1}(p), \quad 0 < p < 1 \quad (6)$$

Assuming that the marginal cdf's F_{X_i} are strictly increasing, one can prove that

$$E[S^c - d]_+ = \sum_{i=1}^n E[F_{X_i}^{-1}(U) - d_i^*]_+ \quad (7)$$

for any d such that $0 < F_{S^c}(d) < 1$, and with the d_i^* given by

$$d_i^* = F_{X_i}^{-1}(F_{S^c}(d)) \quad (8)$$

Notice that $\sum_{i=1}^n d_i^* = d$. The expressions (7) and (8) can be generalized to the case of general distribution functions (see [12] and [13]). An expression similar to equation (7) can also be found in [14] where it is proved that in the Vasicek [15] model, a European call option on a portfolio of zero coupon bonds decomposes into a portfolio of European call options on the individual zero coupon bonds in the portfolio (see **Credit Risk Models; Simulation in Risk Management**).

A Comonotonic Upper Bound Approximation

As opposed to the case of independent or comonotonic r.v.'s X_i , it is, in general, not easy to determine the cdf of S . It may therefore be helpful to find a dependency structure for the random vector $\underline{X} = (X_1, X_2, \dots, X_n)$ that leads to a “less favorable” or “more dangerous” sum of the marginal terms X_i with a cdf that is easier to determine. Decisions based on the “less favorable” distribution are prudent or conservative.

To define what we mean by “less favorable”, we have to decide how to order risks. In this respect, it is convenient to consider convex ordering: A r.v. X is convex smaller than a r.v. Y if $E[X] = E[Y]$ and $E[(X - d)_+] \leq E[(Y - d)_+]$ for all real d . In this case, we write

$$X \leq_{cx} Y \quad (9)$$

In von Neumann and Morgenstern's [16] “expected utility theory”, as well as Yaari's [17] “dual theory of choice under risk”, convex order represents the common preferences of risk averse decision makers when choosing between risks with equal expectations; see, for example [18–20] or [21] (see **Axiomatic Measures of Risk and Risk-Value Models; Optimal Risk-Sharing and Deductibles in Insurance**).

One can prove that for any random vector $(X_1, X_2, \dots, X_n)$ it holds that

$$\sum_{i=1}^n X_i \leq_{cx} \sum_{i=1}^n F_{X_i}^{-1}(U) \quad (10)$$

Hence, replacing S by S^c , and making decisions based on the cdf of S^c can be considered as a prudent strategy. Moreover, quantiles and stop-loss premiums of S^c can be easily determined from equations (6) and (7). The comonotonic upper-bound approximation F_{S^c} will be “close” to the exact cdf F_S when $(X_1, X_2, \dots, X_n)$ has a strong positive dependency structure (see **Credit Risk Models; Reinsurance; Risk Measures and Economic Capital for (Re)insurers**). An insightful geometric proof of equation (10) can be found in [22]. Earlier references to closely related results are [23–25].

Several actuarial and financial problems that were mentioned in the section titled “Aggregating Non-independent Risks” involve the evaluation of the present value or the accumulated value of a series of future cash flows, which can be expressed as a sum S as in equation (1) where the r.v.'s X_i are given by

$$X_i = \alpha_i e^{Y_i} \quad (11)$$

Here, the α_i are deterministic real numbers and $(Y_1, Y_2, \dots, Y_n)$ is a random vector. The accumulated value at time n of a series of future deterministic saving amounts α_i can be written in this form, where Y_i denotes the cumulative logreturn over the period $[i, n]$. Similarly, the present value of a series of future deterministic payments α_i can be written in this form, where now e^{Y_i} denotes the random discount factor over the period $[0, i]$. In both cases (compounding and discounting), the random vector $(X_1, X_2, \dots, X_n)$ will not be comonotonic, although neighboring components X_i and X_j will be rather strongly dependent random variables. This is because there is a natural overlapping process when compounding (or discounting) over the different time periods. A continuous version (with payments continuously spread over time) is considered in [26].

Let us now further assume that $\alpha_i > 0$ and that the Y_i are normally distributed. We find that

$$S^c = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \sigma_{Y_i} \Phi^{-1}(U)} \quad (12)$$

where Φ denotes the standard normal cdf. The quantiles and the stop-loss premiums of S^c are then given

by

$$F_{S^c}^{-1}(p) = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \sigma_{Y_i} \Phi^{-1}(p)}, \quad 0 < p < 1 \quad (13)$$

and

$$E[S^c - d]_+ = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \frac{1}{2}\sigma_{Y_i}^2} \Phi(\sigma_{Y_i} - \Phi^{-1}(F_{S^c}(d))) - d(1 - F_{S^c}(d)), \quad 0 < d < \infty \quad (14)$$

respectively.

For a general random vector $(X_1, X_2, \dots, X_n)$ and real d and d_i ($i = 1, 2, \dots, n$), such that $\sum_{i=1}^n d_i = d$, we have the following result:

$$\left[\sum_{i=1}^n X_i - d \right]_+ \leq \sum_{i=1}^n [X_i - d_i]_+ \quad (15)$$

When the X_i represent asset prices at some future date, say t , then the r.v. $\left[\sum_{i=1}^n X_i - d \right]_+$ can be interpreted as the payoff of a European type basket call option at expiration date t , whereas each of the terms $[X_i - d_i]_+$ can be interpreted as the payoff of a European call option on the i -th asset involved at the same expiration date. The inequality equation (15) provides (*see Equity-Linked Life Insurance; Options and Guarantees in Life Insurance*) an infinite number of ways to superreplicate the payoff of the basket option in terms of the individual asset options involved. The superhedging strategy consisting of buying the n European calls with respective exercise prices d_i^* corresponds to the cheapest super-replicating hedging strategy for the basket option under consideration. Similar results hold for Asian options. For more details, we refer to [2, 6, 27–31].

Comonotonic Lower Bound Approximations

In this section, we look at less crude and hence, better approximations for F_S without losing the convenient properties of comonotonic sums. The technique of taking conditional expectations will help us to achieve this goal.

For an appropriate r.v. Λ , we propose to approximate the cdf of S by the cdf of S^l defined by

$$S^l = E[S \mid \Lambda] = \sum_{i=1}^n E[X_i \mid \Lambda] \quad (16)$$

Notice that a continuous version of this technique applied to Asian option pricing is considered in [32].

Let us now assume that all $E[X_i \mid \Lambda]$ are increasing in Λ . In this case, we find that S^l is a comonotonic sum and the quantiles and the stop-loss premiums related to S^l can be expressed as a sum of corresponding quantities for the individual terms $E[X_i \mid \Lambda]$.

As regards an appropriate choice for Λ , notice that when Λ is chosen equal to S we find that $S^l = S$. Therefore, intuitively it is clear that the “closer” Λ is to S , the better the approximation S^l will perform. However, for the Λ to be useful, we must be able to derive an explicit expression for the different $E[X_i \mid \Lambda]$.

The most prominent case which leads to closed form expressions for quantiles and stop-loss premiums of S^l is the one where $X_i = \alpha_i e^{Y_i}$, with all $\alpha_i > 0$ and $(Y_1, Y_2, \dots, Y_n)$ a multivariate normally distributed random vector. We further concentrate on this particular case.

We choose Λ to be a linear combination of the $Y_1, Y_2, \dots, Y_n$:

$$\Lambda = \sum_{i=1}^n \gamma_i Y_i \quad (17)$$

for appropriate choices of the coefficients γ_i . In the literature, several choices for the γ_i have been proposed, see [13, 33, 34].

For the general Λ , as considered in equation (17), we find that

$$S^l = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \frac{1}{2}(1-r_i^2)\sigma_{Y_i}^2 + r_i\sigma_{Y_i} \frac{\Lambda - E[\Lambda]}{\sigma_\Lambda}} \quad (18)$$

where the r_i are the correlations between the Y_i and Λ .

From equation (18), we see that S^l is a comonotonic sum when all correlation coefficients r_i are nonnegative. Notice that the particular choices for the γ_i , as proposed in [13, 33, 34], lead to nonnegative r_i . The quantiles and stop-loss premiums of S^l are

then given by

$$F_{S^l}^{-1}(p) = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \frac{1}{2}(1-r_i^2)\sigma_{Y_i}^2 + r_i\sigma_{Y_i}\Phi^{-1}(p)},$$

$$0 < p < 1 \quad (19)$$

and

$$E[S^l - d]_+ = \sum_{i=1}^n \alpha_i e^{E[Y_i] + \frac{1}{2}\sigma_{Y_i}^2}$$

$$\times \Phi(r_i \sigma_{Y_i} - \Phi^{-1}(F_{S^l}(d)))$$

$$- d(1 - F_{S^l}(d)), \quad 0 < d < \infty \quad (20)$$

respectively. These results can be generalized. Indeed, in [33] a particular pattern of cash flows with mixed signs of the α_i is considered, whereas in [35] the case that some of the r_i are negative is dealt with. The quality of the upper and lower bound approximations is investigated in [2, 34, 36, 37].

Dependencies in a Non-Gaussian World

In the previous sections, we considered the problem of how to determine comonotonic lower and upper bounds for sums of r.v.'s, and we illustrated the technique for sums of lognormal r.v.'s. We showed that the results can be applied to evaluate risk measures of stochastic net present or accumulated value of future cash flows in a Gaussian world. However, it is well-known that daily returns are correlated and exhibit fat tails, and cannot be adequately modeled through normal r.v.'s. On the other hand, several of the applications we encountered concern long time investment horizons (typically some decades), and hence involve monthly or yearly returns. In this case, assuming a Gaussian model for the vector of cumulative investment returns $(Y_1, Y_2, \dots, Y_n)$ appears to be appropriate, see, for instance [35, 38].

The theoretical developments concerning the comonotonic lower and upper bounds continue to hold for non-Gaussian random vectors. The comonotonic upper bound can readily be applied in the general case. For sums of log-elliptical r.v.'s, we refer to [39]. The performance of the upper bound when Lévy processes are involved is investigated in [27] and [39].

The comonotonic lower bound results are more difficult to use for general distribution functions, mainly because closed form expressions for $E[X_i | \Lambda]$ are often not available. In [3], the lower bound based on the conditioning technique is investigated for sums consisting of a combination of lognormal and normal r.v.'s. The case of sums of log-elliptical r.v.'s is considered in [40].

Comparative Efficacy Trials (Phase III Studies)

A comparative efficacy trial (a phase III study) is a clinical trial (*see* **Randomized Controlled Trials**) that is designed to compare the efficacy (*see* **Efficacy**) of an experimental treatment (e.g., a therapy, preventive agent, or medical device, or any other type of intervention) with that of an active control treatment (or a placebo). Clinical trials to study new treatments are often classified into three successive phases. Phase I trials typically are small studies that are designed to study the safety and toxicity of the new treatment and to estimate the maximum tolerated dose (MTD) of a drug. Once a dose has been determined, preliminary assessments of therapeutic activity and further evaluations of safety are typically carried out in relatively small phase II trials. Phase II trials can include dose ranging studies to identify additional doses and schedules below the MTD that may also be efficacious. Such trials can provide information that can lead to the decision to compare the efficacy of an experimental treatment in large, expensive phase III trials with that of a standard/control treatment [1].

Phase III trials are definitive steps in the evaluation of experimental treatments. They play a pivotal role in the determination of the effectiveness (and/or the incidence and severity of adverse events) of an experimental treatment relative to a standard/control treatment. These trials are usually the third and final step in the test of an experimental treatment, prior to submission of an investigational new drug application (INDA) for approval by relevant governing authority such as the Food and Drug Administration (FDA) of the United States or other relevant governing agencies such as the European Agency for the Evaluation of Medicines.

Phase III trials are, of necessity, often large, and costly, and can require many years to complete. The design of such trials should consider the feasibility of conducting the study in a timely manner. Ongoing monitoring of patients during these trials is required to identify any risks to patients that may be associated with the experimental treatment, as well as to minimize risks of denying patients a treatment that may be truly effective or of exposing patients to an ineffective treatment. Finally, statistical analysis that

incorporates the study design (fixed or sequential), potential patient dropout or noncompliance to treatment, and other issues, is critical to avoid various biases and errors (*see* **Compliance with Treatment Allocation**). Thus, appropriate design, conduct and monitoring, and careful statistical analysis are all important requirements for the eventual success of these important Phase III clinical trials.

This article provides a brief introduction to design and analysis of Phase III trials. The issues discussed include appropriate study designs and patient populations for study, randomization and blinding, selection of efficacy endpoints, the risks of type I and II errors, the determination of sample size, multicenter trials, interim analysis, and the assessment and comparison of treatment effects between/among different treatments.

Design of Trials

In this section, we discuss some common issues that are key to the design of appropriate phase III clinical trials. We restrict our discussion to controlled clinical trials that compare a new treatment or treatments or combinations of treatments or interventions to standard treatment(s) or placebo, or in some circumstances, usual care or observation only.

Randomization and Blinding

In phase III trials, subjects are usually randomized to the treatment arms to avoid selection bias. Selection bias may affect the validity of the comparative study. The randomization may be simple or blocked, and may or may not be carried out in strata. The classic example of a large randomized comparative efficacy trial (phase III) is the Salk vaccine trial of 1954. Over 1 million children participated in the trial. This trial was conducted to assess the effectiveness of the Salk vaccine to provide protection against paralysis or death from poliomyelitis as described in detail by Meier [2]. In one part of this study, 401 973 children were randomly assigned either to injection with the Salk vaccine or with a placebo salt solution. The trial was double blind, that is, neither the children nor the diagnosing physicians were aware of who had received the Salk vaccine or the placebo. Patients and/or their physicians who participate in a study are often blinded to the treatment assignment to reduce

the likelihood of treatment-related bias because of the knowledge of treatment assignment (*see Blinding*). The Salk vaccine trial was conducted in a relatively short period of time, and the endpoints were observed within this relatively short time period. In trials with long accrual times and/or long observation times, to ensure that the effect of an experimental treatment is measured against a comparison treatment administered over the same time period and under similar conditions, a blocked randomization procedure is often used.

Selection of Endpoints

Definitive or surrogate endpoints can be used to assess the effect of the treatment or intervention. If a surrogate endpoint or marker is used, this marker should be correlated with the clinical efficacy endpoint (e.g., survival) and should capture the effect of the treatment or intervention on the definitive clinical endpoint so that it becomes a reliable replacement [3]. For example, in HIV studies, CD4+ counts, which were correlated with the disease, were used as surrogate endpoints for mortality in early AIDS trials; however, when long term follow-up became available, CD4+ counts were not predictive of mortality. Viral load, causally related to outcome, was identified as a better potential surrogate endpoint [4]. In recent studies to examine the efficacy of vaccines for human papilloma virus (HPV) for the prevention of cervical cancer, prevention of infection from HPV was accepted by regulatory authorities as a surrogate for cervical cancer [5]. Thus, the trials were conducted relatively rapidly rather than requiring observation of vaccinated subjects for the development of cervical cancer, a long term endpoint. The association between cervical cancer and HPV has been found to be unique and this link enabled the development of a prophylactic vaccine for cervical cancer [6].

Superiority and Equivalence Trials

Comparative efficacy trials (phase III studies) may be further classified by their primary objectives. These include phase III superiority trials to demonstrate superiority of a new experimental treatment in terms of improved efficacy compared to the efficacy of an active control treatment. Note that, in general, all trials designed to compare a new intervention to a placebo, would be superiority trials. Noninferiority

trials (or equivalence trials), on the other hand, are designed with the objective of showing that the experimental treatment is clinically not much worse than the active control treatment by a specified margin (*see Inferiority and Superiority Trials*). Investigators may decide to conduct a noninferiority trial when they believe that the efficacy of the active control cannot be surpassed, but that the experimental treatment has similar efficacy and may offer important safety and/or cost advantages.

It is common to specify a threshold for the margin of indifference when comparing the treatment effects between the experimental treatment and the control treatment in a noninferiority trial. For example, when comparing the proportion of success in the experimental treatment (P_E) with that of the control treatment (P_C), the noninferiority margin (or the margin of indifference), δ , is often defined as the maximum difference amount by which the experimental treatment is not considered clinically much worse than the control treatment if $P_E > P_C - \delta$. The noninferiority margin δ , should be prespecified and determined on the basis of clinical judgment [7–9].

Let μ_E and μ_C represent the mean value of the efficacy variable for the experimental and control treatment, respectively. Further, suppose that positive values of the parameter of interest (or values greater than one, in case of a ratio) indicate superiority of the standard treatment. The standard null and alternative hypotheses for testing noninferiority are,

$$\begin{aligned} H_0(-\delta) : \mu_C - \mu_E &\geq \delta \quad \text{versus} \\ H_1(-\delta) : \mu_C - \mu_E &< \delta \end{aligned} \quad (1)$$

where $\delta > 0$ is the noninferiority margin, that is, the amount by which μ_C can exceed μ_E with the experimental treatment still being considered noninferior to the active control. The null hypothesis states that the active control μ_C exceeds the experimental treatment μ_E by at least δ ; if this cannot be rejected, then the active control is considered superior to the experimental treatment with respect to efficacy. The alternative hypothesis states that the active control may indeed have better efficacy than the experimental treatment, but by no more than δ . In such a case, we say the experimental treatment is not inferior to or no worse than the active control. Thus, rejection of the null hypothesis

concludes noninferiority. For superiority trials, the hypotheses can be formulated as above by letting $\delta = 0$ in equation (1).

Power and Sample-Size Analysis

In the design of phase III clinical trials, in addition to selecting the appropriate randomization procedures and/or blinding methods, one must also guard against the risk of committing any of the two common types of errors in typical hypothesis-testing-based trial designs. A type I error is made if the study leads to a false rejection of the null hypothesis H_0 , and a type II error is made if the study fails to establish the alternative hypothesis H_1 when it is indeed true. The probabilities of type I and type II errors are often denoted by α and β , respectively. The statistical power of a test is defined as the probability $1 - \beta$.

In the design of a phase III trial, the investigators often have some idea of the order of magnitude of the efficacy difference that they consider clinically meaningful. A difference, Δ , between the projected efficacy for the experimental treatment and that for the control treatment, that is worth detecting is often specified [10]. The primary efficacy endpoints often have normal distributions. The sample size needed to compare the means of two normal distributions with equal and known variances σ^2 , using a one-sided z -test, can be obtained as

$$n_C = \frac{\sigma^2(z_\alpha + z_\beta)^2[1 + 1/k]}{\Delta^2}, \quad n_E = kn_C \quad (2)$$

where one sample (n_E) is k times as large as the other sample (n_C), σ^2 is the common variance and Δ is the minimum meaningful difference between the means (say, μ_C and μ_E) to be detected, and z_α and z_β are the upper percentiles of the standard normal distribution corresponding to α and β . Additional details on sample-size formulas for various efficacy endpoints can be found in many sources [1, 9, 11, 12]. Similarly, the sample-size estimation procedure for the design of noninferiority trials can be found in many textbooks and classical papers [1, 9, 13, 14].

Multicenter Trials

Phase III trials, in general, are large, and, of necessity, are usually conducted at multiple sites. Multicenter trials can yield results that could be applicable to

a wider range of treatment settings or patient groups than a single center trial [15]. Such trials should allow the investigators to estimate an overall treatment effect in the patient populations under study at the various sites. The multicenter trial, while generally expedient, incorporates some particular difficulties in the conduct and implementation that require attention in both the design and analysis stages. In particular, critical for the successful completion of a multicenter trial, are the development of the protocol that specifies accrual requirements from each center, details of patient management, criteria for patient entry and randomization, details of treatment regimens, criteria for patient evaluation and for alterations in planned patient management, procedures to ensure consistency across centers, and definitions of response and endpoints along with documentation requirements.

Analysis of Trial Outcomes

The approach to the comparison of different treatment effects depends on the primary outcome measurement. The comparison in the case of an event, such as death or recurrence of disease, is based on the event rate for different treatment groups. In case of a continuous outcome, such as weight or blood pressure, the change from baseline to some defined point after enrollment is determined for each subject and then summarized using means or medians. The treatment effect is estimated as the difference between the change in mean or median from the baseline for the control and experimental groups.

Frequently, a formal hypothesis test is conducted to compare the efficacy of the competing treatments based on data from the trial. In practice, a two-sided test is often recommended, even though the investigators are often only interested in a one-sided alternative hypothesis [10]. The efficacy parameter can be estimated and its confidence interval obtained for each treatment arm. The efficacy differences among treatment groups can be evaluated using appropriate measures such as, the difference in response rates, hazard rates, means or median survival times, etc., along with corresponding confidence intervals [1, 10, 12].

Statistical analysis that appropriately incorporates the planned trial design (fixed or sequential designs), data monitoring and interim analysis results, patient dropout and noncompliance to treatments, misclassification errors [10, 16], and other issues is essential

to the final success of a clinical trial. The subsequent discussion focuses only on a few of the most common issues that arise in the analysis of clinical trials.

Sequential Designs and Interim Analysis

Trials are either designed with a fixed or sequential/group sequential sample size. Most phase III trials use fixed sample size, i.e., the sample size is specified at the start of the study. In sequential trials, enrollment and observation continues until a stopping boundary is crossed. Inference about the treatment effect in sequential designs has to consider the fact that the stopping time of the trial is random, in order to avoid bias. Methods for the design and analysis of phase III trials using group sequential procedures with interim analysis are described in Proschan et al [17]. The two most common approaches are (a) O'Brien–Fleming boundaries that permit early stopping for success with very stringent α -level requirements and maintain almost all of the α level for the final planned look [18], and (b) Pocock boundaries that divide the α level equally among the planned looks, making it easier to stop the trial early [19]. These approaches fall under the class of Lan–DeMets spending function approach with different parameterizations [20].

Repeated Measures Analyses

Repeated measures data arise when multiple measurements of response variables and/or covariates are obtained from each experimental unit over the duration of the clinical trial. The repeated measures design (e.g., the crossover design) provides opportunities for investigators to examine the pattern of response variable under different measurement occasions, to understand the relationship between repeated outcomes and treatments as well as covariates, and to discern the dependence pattern among the repeated measurements. A special feature of repeated measures data is that the measurements from the same unit are usually positively correlated; thus, valid and effective analysis of repeated measures must incorporate this within-subject correlation (*see Repeated Measures Analyses*).

Analysis of Multicenter Trials

In multicenter trials, randomization is usually carried out within centers (strata) to ensure balance among

treatment groups within centers and to take into account the subtle differences among centers with respect to interpretation and implementation of the protocol, equipment, supportive care, and patient populations. As a consequence, the final analysis will generally incorporate the center effect as a fixed effect (weighted by center or unweighted) or as a random effect [15]. The discussion of the implication of unequal center sizes on the treatment-by-center interaction term in the regression modeling framework can be found in Gallo [21]. In this sense, the multicenter trial analysis can be considered to be a meta-analysis that combines results from different centers [22].

Missing Data and Noncompliance

Patient dropout and/or noncompliance to assigned treatments are common in large clinical trials with differing efficacy, and/or side effects for the treatments under study, as well as in trials with long durations. For example, survival time data arise frequently in many clinical trials, where incomplete or censored observations are common due to multiple factors. Statistical methods and models for survival analysis such as Cox's semiparametric proportional hazards models are widely used. Per-protocol based analysis may be compared to per-randomization based analysis to avoid biased analysis and interpretation of the data [1, 12].

This article provides a brief discussion on the design and analysis of phase III clinical trials. An in depth discussion of various issues is beyond the scope of this short review. Fortunately, there are a large number of monographs and textbooks about phase III trials. Interested readers can consult these useful reference books.

Comparative Risk Assessment

In its most general sense, comparative risk assessment (CRA) is an analytical process of (a) defining a type of undesired outcome, e.g., human mortality, (b) selecting a location, e.g., worldwide, (c) gathering information on factors relevant to that outcome, e.g., infectious disease and environmental toxins, and (d) ranking these factors in terms of their relative importance or contributions to the undesired outcome. Importance can be ranked either in terms of the expected harm or the potential for reduction in harm from controlling the different sources being compared. The term *comparative risk assessment* is more frequently used in the context of environmental risk (see **Environmental Health Risk**), but the principles and methodology are applicable in other contexts.

CRA is both a scientific and a political process. Scientific methods are used to gather data, classify the type and severity of risks, and identify and verify relationships between outcomes and risk factors. CRA is not intended as an academic or purely scientific exercise. It is a guide to decision making and, therefore, also involves the political functions of defining the scope of the assessment, determining the stakeholders and involving them in the process, and putting the results into a context that can be effectively communicated and used to develop consensus concerning appropriate action (see **Role of Risk Communication in a Comprehensive Risk Management Approach; Stakeholder Participation in Risk Management Decision Making**).

This article will review the history of CRA for environmental risk, discuss methods of risk ranking used in environmental risk, review methods of communicating risk, look at a few examples of CRA in nonenvironmental areas, and touch on United States Environmental Protection Agency (USEPA) and other regulations, as they relate to CRA.

Comparative Risk Assessment in Environmental Risk

History of Comparative Risk Assessment in the United States

Formalized CRA is a relatively young field, with documented uses by public agencies beginning in

the 1980s. A brief timeline on CRA milestones is as follows.

In 1981, the USEPA used comparison of the rate of occupational injury in retail trades, i.e., a safe occupation, to help set the allowable level of occupational exposure to radiation [1].

In 1983, the US National Academy of Sciences published the study “Risk Assessment in the Federal Government: Managing the Process” [2]. The focus of this work was to breach the gap between scientific information and public policy as they relate to the potential health effects of toxic substances, with primary focus on increased risk of cancer due to chemicals in the environment. The report recommended that a clear distinction between risk assessment and risk-management policy be maintained and that explicit guidelines for the process of risk assessment be published.

In 1985, the US Occupational Safety and Health Administration (OSHA) used the comparison of rates of job-related illness for firefighters, miners, and other high-risk occupations and rates for low risk occupations such as service employment to help determine if the estimated risk associated with benzene exposure (see **Benzene**) was sufficiently high to be considered “significant” [3].

The US Environmental Protection Agency Task Force was established in 1986. This task force published “Unfinished Business: A Comparative Assessment of Environmental Problems – Overview Report” [4–8]. The concept of comparative ranking of risk to human health was clearly established in this work. A team of 31 EPA scientists and managers ranked 31 environmental problems in terms of: (a) human cancer risk, (b) human noncancer health risk, (c) ecological risk, and (d) welfare risk. This report noted that public perception of risk does not always match risk ratings of scientists, and that public policy is frequently driven by public perception of risk. The US Science Advisory Board responded to “Unfinished Business” with “Reducing Risk: Setting Priorities and Strategies for Environmental Protection” in which they recommended broad public participation in the ranking of risks, emphasizing the uncertainty in many scientific risk assessments.

In 1993, the Carnegie Commission on Science Technology and Government published “Risk and the Environment: Improving Regulatory Decision Making” [9], recommending placing problems in broad risk categories, developing multidimensional

risk rankings, and finding methods to integrate societal values into relative risk analyses. The use of relative or comparative risk rankings was also recommended in the 1995 Harvard Center for Risk Analysis report, "Reform of Risk Regulation: Achieving More Protection at Less Cost" [10].

By 1997, the Presidential/Congressional Commission on Risk Assessment and Risk Management was explicitly recommending that "(US government) agencies should use a comparative risk assessment approach for risk management on an experimental or demonstration basis to test the effectiveness of seeking consensus on setting priorities for environmental, health, and safety hazards" [11].

Examples of Comparative Risk Analysis Projects

CRA projects range from very general to very specific. The examples listed here are by no means exhaustive. We start with further detail on the groundbreaking "Unfinished Business", followed by an example so general as to tackle worldwide health risk, and end with examples specific to a type of risk (cancer) and to a small number of risk factors. Further narrowing of the scope is illustrated by examples specific to a product or specific to a location.

A widely cited example of environmental comparative risk analysis is the study by the USEPA of 31 environmental risk factors documented in the 1987 report "Unfinished Business: A Comparative Assessment of Environmental Problems – Overview Report". Working groups were established to evaluate and rank 31 specified environmental problems in each of the four risk categories: (a) human cancer risk, (b) human noncancer risk (c) ecological risk, and (d) welfare risk. The concept of a risk ranking method in which the concerned public and other stakeholders as well as scientists were engaged in the ranking process was established here as well.

The cancer risk group ranked worker exposure to chemicals (formaldehyde, tetrachloroethylene, asbestos, and methyl chloride) and indoor radon (see **Radon**) as the highest environmental problems, followed by pesticide residues on foods (herbicide, fungicide, insecticide, and growth regulator), indoor air pollutants other than radon (tobacco smoke, benzene, *p*-dichlorobenzene, chloroform, carbon tetrachloride, tetrachloroethylene, and trichloroethylene), and consumer exposure to chemicals (formaldehyde, methyl chloride, *p*-dichlorobenzene, and asbestos).

The ecological risk group gave *stratospheric ozone depletion* (see **Stratospheric Ozone Depletion**) and CO₂ the highest rank followed by physical alteration of aquatic habitats, mining, gas and oil extraction, processing, and wastes.

The World Health Organization's 2002 World Health Report is an example of a comparative risk analysis at the most general level. Risks evaluated include: malnutrition and underweight, unsafe sex, high blood pressure, tobacco, alcohol, unsafe water and sanitation, high cholesterol, indoor smoke from solid fuels, iron deficiency, overweight, zinc deficiency, low fruit and vegetable intake, vitamin A deficiency, physical inactivity, and many others. Risks were ranked according to estimated disability-adjusted life years (DALYs) lost attributable to the risk factors. The global exposure to these risks and the relationship of these exposures to poverty and socioeconomic status was evaluated. Rankings were produced for developing and developed countries, and show that a relatively small number of risk factors "cause a huge number of premature deaths and account for a very large share of the global burden of disease" [12].

An analysis of the causes of cancer in the world is an example of a CRA of nine behavioral and environmental risk factors [13], where the scope of the analysis was narrowed with a detailed follow-up of risk factors identified and ranked in a larger, more global analysis. Mortality from 12 types of cancer was evaluated with a focus on potentially modifiable risk factors. The authors judged that 35% of worldwide cancer deaths could be attributed to the nine factors: smoking, alcohol use, low fruit and vegetable consumption, overweight and obesity, physical inactivity, sexual transmission of human papilloma virus, urban air pollution, indoor smoke from household use of solid fuels, and contaminated injections. These risks were ranked as the nine most important cancer risks that could be mitigated or removed.

An example of using CRA to evaluate a very specific health risk is the US Food and Drug Administration's estimate of the risk of *Escherichia coli* O157:H7 per serving of tenderized beef as compared to nontenderized beef [14] under various cooking conditions. A probability model for estimating the transmission of *E. coli* from cattle to consumer was used to find essentially the same risk of illness per serving of tenderized beef as for nontenderized beef.

An example of comparative risk analysis with a very specific location is “Chelsea Creek Community Based Comparative Risk Assessment” [15] in which five community organizations and the USEPA used CRA to provide information to improve public health for residents of the area. Community surveys were used to identify 15 top issues ranging from air pollution, trash, and water quality to housing and health care insurance.

Comparative Risk Assessment in Practice

The following sections describe details of the CRA method. While developed in relation to environmental risks, this methodology is general enough to apply to any type of risk assessment. The steps of the methodology as well as methods of communication of the results are described.

Components of Risk

Any CRA must start with a specification of the types of risks to be studied. Historically, environmental risk assessments focused upon human cancer risk associated with toxic chemicals. Other risks considered are human noncancer risk, ecological risk, and quality of life risk (or welfare effects). Both human cancer risk and human noncancer risk can be measured in terms of number of deaths per year. This can be refined as DALYs lost, giving higher value to a life lost at an early age. Ecological risk is measured by changes in basic characteristics of the ecosystem as a whole, and this assessment will depend upon the ecosystem being considered. Welfare or quality of life risk is measured as decline in economic value or value of other human activity other than health-related decline.

Risk Ranking

Once all relevant risks have been identified, the risks are ranked from the most important to the least important. The ranking may be done by discussion or other group dynamic processes leading to consensus; this could include taking of straw polls and additional discussion until the group decision becomes stable. For larger groups or groups that do not meet face to face, a simple majority rule vote could be used to rank the risk. For example, each person is given an equal number of votes to be allocated among the

various risks. The risk receiving the largest number of votes is given the highest rank and so forth. For risk assessments for which there is sufficient information concerning both the rate of death, illness, or injury per unit of exposure, as well as data on the distribution of the amount of exposure, a formula can be used to rank the risk factors. Examples of formulae used in risk ranking include estimated annual number of cancer deaths, estimated annual number of serious or fatal injuries, and estimated DALY lost.

Whichever method is used for the risk ranking, the uncertainty in the estimates of risk per unit of exposure and in the estimate of amount of exposure should be considered in the assignment of ranks. This can be done informally in the consensus or voting process or formally by calculating confidence intervals around the risk estimate calculated using formulae.

There were four EPA working groups, one for each component of risk considered in “Unfinished Business”. The ranking methods used by these four groups illustrate approaches to the ranking process.

The cancer risk group at first used available data to partition the problems to be considered into five broad categories of importance. This was followed by ordinal ranking within each category. Ordinal rankings were refined by an iterative consensus process.

The ecological risk working group noted that a quantitative model-based approach to ranking works for well-defined problems, but is less useful for broadly defined problems. This working group started by defining four general categories of ecosystems and evaluating how the 31 environmental problems identified by the USEPA are related to the four ecosystem categories; nine of the 31 environmental problems were dropped from further study in the first screening. The group then formed a preliminary rating of the remaining 22 environmental problems within each of the ecosystem categories using a three-point (high, medium, and low) scale. A background paper was prepared for each of the 22 problems; each workgroup member used this information to rank the problems. Consensus was reached by a final classification of the problems as high, medium, or low without further ranking within these levels of importance.

One primary value of consensus ranking is that the fact of consensus in the ranking of risks may generate the political will to go to the next step and begin to

take action. However, as in any group decision process, the group consensus need not generate optimal or even good decisions. Although risk ranking may consider the likelihood of actions for risk reduction during the ranking process, it may not be possible to adequately capture the importance of budget constraints in the ranking process. This is particularly true when some of the possible risk reduction actions are mutually exclusive or when possible expenditures of funds are not continuous. For example, consider the situation in which action A is expected to save 10 lives per \$ million expended, but at most 30 lives could be saved (\$3 million total cost), while action B could save only 8 lives per \$ million spent but could save 40 lives (\$5 million total cost). If a total of \$5 million is available, and it is not possible to spend the first \$3 million on action A and the remaining \$2 million on a partial implementation of action B, then action B, which has the higher cost per life saved, may be optimal.

Project Teams

CRA is distinct from the risk-management process; it is generally intended to be a source of information for the subsequent risk-management decisions. It is often recommended that the project team include representatives of all of the stakeholders. Team members may include scientists, members of regulatory agencies, public health officials, members of planning commissions, representatives of business or citizens groups, and other interested individuals. This process may take longer than simply producing scientific estimates, but it is likely to be more efficient and to actually provide the type of information that will lead to decisions to take action to mitigate risk. Even in those situations in which formulae are to be used to create the rankings, the group process is used to determine the formulae that are used for the ranking.

Communication through Comparison to Known Risks

Every product and every human activity carries with it some level of risk. The concepts of CRA can be used to communicate the importance of a risk of interest by comparing the level of risk for similar products or activities. Some of the earliest uses of CRA were of this type. As previously noted, in 1981 the USEPA used comparison to familiar risks

to set levels for allowable occupational exposure to radiation, and in 1985 the US Occupational Safety and Health Administration used comparison of injury levels in high-risk jobs to conclude that benzene exposure was a significant risk.

This type of comparison is most useful if the risks to be compared can be put on the same scale, e.g., risk of injury per million exposure hours. The chart in Figure 1 shows the risk of injury for various recreational activities in the United States.

The US Consumer Product Safety Commission uses this type of approach. For example, the risk of injury for skateboards was put into context by comparing it to the injury risk associated with roller skates, ice skates, and similar types of products [16]; the injury risk associated with chain saws was compared to injury risk associated with walk-behind power mowers [17]; the risk of drowning in a home swimming pool for children under age five was compared to the risk of death for children under age five in spas, motor vehicle crashes, and all home accidents [18].

The comparative risk method can also be used to evaluate the relative safety of competing products and to address questions of unreasonable product risk. For example, the year 1993–1995 Honda Civic Coupe model was alleged to have an unreasonably high risk of injury for occupants involved in side collisions [19]. Data from police reported side collision crashes was used to make a CRA of the risk of injury in side collisions for occupants of the Honda Civic Coupe and occupants of other passenger vehicles of similar age and size. This information was useful to the jury in deciding that the Honda Civic was not defective (see Figure 2).

Comparative Risk Assessment in Nonenvironmental Areas

While the use of CRA, particularly the group or team approach, has seen wide use in environmental issues, the basic concept of comparing different risks for the purpose of making risk-management decisions is applicable in any situation in which relevant data can be collected and there is interest in making informed choices. The value of comparative risk is perhaps easier to appreciate when the area for risk assessment is narrowly defined and the appropriate risk-management decision is straightforward. A few examples on nonenvironmental risk assessment follow.

¹Exposure hours computed for operators from "ATV owning households" only.

Figure 1 Comparative risk assessment of injury for recreational activities. *Notes:* Risk is the number of injuries per million exposure hours. The ATV risk estimate is based on data from 1989. All other activities have risk estimates based on from 1990. All injury estimates reflect the US Government's revision of the hospital emergency room sampling frame in 1990

CRA of Hazmat and Non-Hazmat Truck Shipments [20] used the following CRA method: (a) arrange Hazmat classes into categories, (b) estimate incident likelihood for each category, (c) estimate per incident economic impact, (d) calculate annual risk, and (e) estimate annual risk for non-Hazmat categories and compare. They found the cost of Hazmat transport accidents to range from \$0.05 to \$0.42 per mile. In comparison, non-Hazmat transport accident cost was estimated at \$0.25 per mile.

The US Department of Transportation Federal Railroad Administration used CRA to evaluate the risk of conventional switching operations with remote control switching [21]. A human reliability assessment of potential operator errors was used to compare the risks associated with the two switching methods.

The FDA/Center for Food Safety and Applied Nutrition in conjunction with the USDA/Food Safety and Inspection Service, and the US Centers for Disease Control and Prevention conducted a CRA of 23 ready-to-eat food categories as they relate to the foodborne illness caused by the bacterium *Listeria monocytogenes* [22]. This bacterium causes serious illness and fatality in high-risk groups of people such

as the elderly and persons with compromised immune systems. Two dimensions of risk were considered in the ranking process: (a) risk of illness per serving and (b) annual number of cases in the United States. A cluster analysis algorithm was used to classify each of the 23 food groups into five risk categories. The very high-risk category (e.g., deli meats) is high on both dimensions of risk, has high rates of contamination, and supports rapid growth of the bacterium under refrigeration. The high-risk category (e.g., pate and meat spreads) is high on either risk per serving or number of cases per annum and supports growth of the bacterium during extended refrigerated storage. The moderate risk category (e.g., fruits and vegetables) contains foods that are of medium risk both per serving and number of cases per year. For these products, the risk is primarily associated with recontamination. The low risk category (e.g., preserved fish) contains foods that have moderate contamination rate, but include conditions such as short shelf life that are expected to reduce the risk of bacterial growth. The very low risk category (e.g., hard cheese) includes products that have low contamination rates and characteristics that either inactivates or prevents the growth of the bacteria.

Figure 2 Comparative risk assessment of crashworthiness. *Source:* Combined state analysis: Alabama 1992–2000, Florida 1992–2000, Maryland 1992–2000; passenger car model, years 1991–1996

This is an excellent example of the use of a statistical method (cluster analysis) to handle multiple dimensions of risk to produce a meaningful risk ranking algorithm.

Comparative Risk Assessment Issues

Criticisms of the Comparative Risk Assessment Process

Several specific criticisms of the CRA process are discussed here.

Most risks are by nature multidimensional, and direct comparison is not meaningful, i.e., apples cannot be compared with oranges [23, 24]. Finkel [25] recommends explicit recognition of the multiple value systems that can be used to rank risks and delineation of the common aspects of the risks during the ranking process. For example, apples and oranges can be compared on price per pound, calories per

serving, and many other factors. Humans regularly make comparisons between disparate situations, e.g., “Should we go to a movie or spend the evening at a fine restaurant?” Consequently, the multivariate nature of many risks is not necessarily a bar to meaningful comparisons. Kadvany [24] recommends the formalization of this comparison through the use of multiattribute utility theory, a method of aggregating multiple dimensions into a single dimension by assigning weights to each dimension and taking a weighted average, or other function that combines the multiple dimensions. The difficulty is, of course, finding an appropriate weighting scheme so that the linear function is a reasonable representation of the utility of reducing the risk, or in cases in which no linear combination is appropriate identifying a function that both combines information from all of the dimensions and is useful for comparing the overall magnitude of the risk. (See the previous example for a discussion of the use of cluster analysis as a

means of combining the different dimensions of risk of foodborne illness [24].) The fact that CRA projects frequently rank the risks through voting or group consensus methods is an informal way of integrating the multiple components of risk.

Information is Frequently Incomplete. Some level of uncertainty is inherent in any risk analysis and in most decision making processes. Kavadhan [24] recommends distinguishing between uncertainty, i.e., incomplete knowledge, and variability, i.e., the risk factor has differential effects in different circumstances. Rather than reporting only point estimates of risk (e.g., five deaths per million exposed persons per year) report confidence bounds, (e.g., with 95% confidence the risk is between one and nine deaths per million). In this way, ranking of risk can be based upon both the estimated level of risk and the uncertainty associated with the risk.

The complexity of scientific methods for estimating the magnitude of various risks makes it difficult for the concerned public to evaluate the validity of the estimates [23]. The method of risk ranking based upon voting or group dynamic processes mitigates this criticism. The scientifically based numerical estimates of the level of risk provide part of the raw material for risk ranking. If representatives of all stakeholders are included in the process, the end result will not be dominated by the mathematical estimates of risk.

Risk Ranking does not go Far Enough. Risks should be ranked not according to the highest level of risks, but according to the highest level of preventable risks or according to the most cost-effective reduction of risks [24]. There is nothing in the concept of ranking risk that prevents consideration of the cost of reducing the risk as one of the attributes in the ranking process. As noted by Gutenson [26], comparative risk processes can lose their “distinct identity” and become simply a state or locally driven risk-management process.

Comparative Risk in the United States and Europe

The comparative risk process involving ranking of risks by a team of scientists, community members, business interests, and other stakeholders has been

recommended by the USEPA since the 1987 “Unfinished Business” report outlined the method.

In 2006, the US Office of Management and Budget (OMB) [27], in consultation with the Office of Science and Technology, proposed to issue new guidance on risk assessments in the form of a Risk Assessment Bulletin. The purpose of the bulletin is to “enhance the technical quality of and objectivity of risk assessments prepared by federal agencies by establishing uniform minimum standards”.

The proposed bulletin recommends making the purpose of the assessment clear by distinguishing between screening level risk assessments and comprehensive risk assessments. Five goals are enumerated: (a) the project problem should be formulated through iterative dialogue with the decision makers who will use the risk assessment. (b) The scope of the assessment should balance scientific completeness with the information needs of the decision makers; the costs and benefits of acquiring further information should be considered. (c) The level of effort should be commensurate with the importance of the risk assessment. (d) Agencies should consider the importance of the risk assessment in allocating resources. (e) Appropriate procedures for peer review and for public participation should be used. At the request of the OMB, the National Research Council reviewed the proposed bulletin and recommended that the current draft bulletin be withdrawn, and replaced with a bulletin that outlines general goals and principals of risk assessment and directs federal agencies to develop their own technical guidelines [28].

In contrast to the United States, CRA is not so widely used by European governments. Examples of CRA in Europe include the following:

The European Commission has funded a study of food safety in which CRA will be used to improve current risk analysis practices for food produced by different breeding approaches and production practices [29].

In 2003, the International Risk Governance Council (IRGC) recommended development of databases and methodology for CRA in its report of IRGC activities for the part-year June 2003–December 2003 [30].

The World Health Organization has adopted CRA in its assessments of selected major risk factors and global and regional burden of disease [12].

Compensation for Loss of Life and Limb

Each year, approximately one in six Americans suffers economic losses caused by nonfatal injuries. The direct and work-loss costs associated with these injuries total close to 4% of the US gross national product (GNP) [1]. In addition, approximately 1 in 2500 Americans dies each year from an unintentional injury [2].

This article discusses the direct economic costs, indirect economic costs, and noneconomic costs associated with injuries and fatalities. Different methods for putting a value on noneconomic costs, often referred to as *pain and suffering*, are compared, and the types of compensation available for these different costs, including private insurance, public insurance, and the tort system, are examined. Next, a detailed discussion of how the tort system treats compensation for loss of life and limb is given. Finally, this article considers how life and limb are valued in other contexts, such as setting government regulations and assessing health care priorities. The focus is on the United States.

Injury Statistics

Approximately 50 million Americans suffer economic losses each year caused by nonfatal injuries. Of these persons, approximately 75% experience an economic loss from an injury that occurred the same year, whereas 25% experience an economic loss from an injury that occurred in a previous year. The breakdown of the source of injuries among these persons is given in Figure 1.

The work-loss associated with these injuries is significant. Overall, more than 6% of employed adults lose time from work each year owing to injuries [1].

In addition, there are 170 000 fatal injuries in the United States each year, of which 70% result from accidents. The remaining 30% are violence related [2].

Components of Loss

Accident victims suffer various types of loss associated with their injuries. Economic costs include

medical expenses and other direct costs, such as special equipment and home help. These direct costs account for more than half of the economic losses associated with nonfatal injuries. In addition, there may be losses because of the individual's inability to continue with some or all work activities, as well as lost wages of family members who curtail work to care for the injured [1].

Further, there are noneconomic losses, including inability to perform nonmarket activities (e.g., attending school, caring for children, participating in hobbies), loss of enjoyment of life, and the fact that money has less utility if the injured person cannot use it for the things he/she has used it for in the past. For example, the money that used to buy a person the enjoyment of a concert can no longer bring that pleasure if the person becomes deaf.

Economic losses are much easier to value than noneconomic losses. In particular, placing a value on loss of enjoyment of life, referred to as *pain and suffering* in the legal lexicon, has proved to be particularly challenging.

Valuing Life and Limb

Valuing Life

Historically, valuations of life were based on human capital theory. A life was valued by future production potential, generally calculated as the present discounted value of expected future earnings [3]. This

Figure 1 Nonfatal injuries resulting in economic loss in the United States

captured the economic component of loss, but did not address the noneconomic component.

The “hedonic” value of a life refers to the value of life itself, for the pleasure of living, independent of earnings potential. This type of value is much harder to quantify. Beginning in 1968, researchers have gone on to measure the implicit value of life by examining human behavior.

Economists infer value from revealed preferences – i.e., by observing how people actually behave. Some may assert that life has an infinite value, but if that were true, people would avoid dangerous activities whenever possible, eat only healthful foods, and so on. Thus, although there may not be a clear trade-off between life and monetary amounts, it is clear that people do make trade-offs between various pleasurable activities and the risks to life and limb that go along with those activities.

One way that economists measure how much people value life is by studying the wage premium for risky professions: how much extra compensation is required to convince people to take on riskier jobs? In various studies, economists have estimated the risk of death in dangerous jobs and compared the wages to those from safer jobs that are otherwise similar. The difference in wages between those jobs, divided by the extra risk of death in the more dangerous job, gives a measure for the value of a statistical life (VSL). The VSL estimates derived in this way are generally in the \$2 million to \$12 million range (US \$2000) [4–6].

Criticisms of this method are that dangerous jobs and safer jobs are never actually equivalent, with the only difference being the risk level (for example, there may be tension associated with higher risk jobs). Also, the people who are willing to take on more dangerous jobs may be those who place a lower value on their lives or who are relatively risk tolerant or risk seeking [7]. Hence, their revealed VSLs are not necessarily applicable to other people.

Other ways to measure the value of life involve evaluation of the choices that people make, which affect their risk of death or injury. Studies have examined the price-risk trade-off for automobile safety, seat belt use, bicycle helmets, cigarette smoking, smoke detectors, and property values in polluted areas. Such studies yield VSL estimates that range from approximately \$1 million to \$10 million (2000 US \$). These estimates tend to be a little lower,

although on the same order of magnitude, as those obtained from labor market studies [4, 8].

Although these measures are imperfect, they may provide a useful starting point for VSL calculations. But such measures should not be taken literally, since a body of evidence suggests that people do not have accurate perceptions of risk and so may not make fully informed choices [9]. Also, VSL estimates based on willingness to pay (WTP) naturally vary with income, since those with lower income cannot afford to pay as much for increased safety. Moreover, VSLs estimated from these studies reflect the preferences of the particular population in the study and so should not be considered a universal constant.

Valuing “Limb”

Value of life estimates obtained from revealed preferences may be coupled with assessments of the relative quality of life for different health states to get a measure of the “value” associated with different types of injuries.

In economics, utility reflects the satisfaction gained from different alternatives. Measuring health utilities involves defining a set of health states and having people provide judgments on the relative desirability of time spent in these different states. Methods of soliciting such judgments include the standard gamble, time trade-off, rating scales, and WTP [10].

The standard gamble (or “hypothetical lottery”) procedure is a classic method of measuring preferences (or, more accurately, von Neumann–Morgenstern utilities) in economics. It makes use of a hypothetical lottery to measure people’s utilities, which reflect preferences for outcomes and attitude toward risk. The lottery typically involves a choice between two alternatives: (a) a certain outcome or (b) a gamble giving some probability of obtaining a better outcome and a complementary probability of ending up with a worse outcome. The stakes and/or odds in the lottery are shifted until the person is indifferent between the hypothetical lottery and the certain outcome.

The time trade-off method was developed as a simpler alternative to the standard gamble. It trades off the quality of life against the length of time alive.

Another simple technique is a rating scale. This can take on various forms. An example is a visual analog scale consisting of a single line with the best

possible health state (perfect health) with a score of 1 and the worst possible health state (generally, death) with a score of 0. This is shown in Figure 2.

Respondents are asked to place various health states on the line at the positions the respondent thinks are appropriate. Health state utilities derived from the rating scale are consistently lower than those obtained by either standard gamble or time trade-off [10].

In Europe, the EuroQol EQ-5D is a questionnaire that is used to assess people's utility for different health states [11].

It should be noted that there are significant caveats to all of these methods. Health utilities are extremely subjective measures and may vary widely based on the measurement method (e.g., wording of questions asked and allowed responses in a survey), as well as the population being surveyed. For example, different studies have estimated the health utility for depression between 0.3 and 0.99, depending on how depression is defined and what population is being studied [12].

A catalog of health state preference scores obtained in different studies is maintained by the Tufts Cost-Effectiveness Analysis (CEA) Registry [12]. Some examples of preference scores for different health states, as listed in this registry, are given in Table 1.

To calculate the hedonic value of an injury in monetary terms, one could start by finding the loss in quality of life associated with that injury. For profound deafness, this could be calculated as 1

(state of perfect health) minus 0.6 (utility associated with profound deafness), giving 0.4. If this state is assumed to last for the rest of the person's life, and if the length of life is assumed to be unchanged from what it would have been without the injury, then the "value" of the injury could be taken as the loss in quality of life multiplied by the value of a life. For example, if a life is taken to be worth \$5 million, then the "value" of profound deafness might be estimated, very roughly, as $0.4 \times \$5 \text{ million} = \2 million . Of course, adjustments should be made for age, since a young person who is permanently injured must live with the affliction for many more years than an older person. Also, the calculation might include a discount rate to convert to present value.

Compensation Systems

Sources of Compensation

Accident victims may seek compensation for their losses from a variety of sources. The starting point is often the person's own private insurance – for example, health, automobile, accident, or disability insurance. If the person has been injured on the job, the person may seek workers' compensation. There may also be employer benefits such as paid sick leave. In addition, there are multiple public insurance programs that assist victims, including the National Vaccine Injury Compensation Program, unemployment benefits, and supplemental security income, among others. These types of compensation are generally "no fault" – they compensate the victim regardless of who was at fault in causing the injury.

If the victim believes that another party is responsible for the injury, he/she might seek liability compensation. The percentage of persons seeking liability compensation for different types of accidents is given Table 2 [1].

Although only 1 in 10 injured Americans with economic loss attempts to collect liability payments from the injurer or the injurer's insurance, this rate varies widely with the type of accident. The claiming rate for persons injured in motor vehicle accidents is more than 6 times higher than that for work accidents and almost 15 times higher than that for other nonwork accidents. A contributing factor to the lower claiming rate for work accidents is that in most cases, employees receiving workers' compensation are barred from seeking liability compensation.

Figure 2 Visual analog rating scale

Table 1 Selected health state preference scores from the Tufts CEA Registry

Health state	Preference score (0–1)
Blindness	0.4–0.7
Trouble hearing	0.8
Profound deafness	0.6
Below knee amputation	0.6–0.8
Manual wheelchair	0.7
Electric wheelchair	0.8
Disability in bed	0.4

Table 2 Percentage of persons with economic loss arising from nonfatal injuries who make liability claims in the United States^(a)

Type of accident	Percentage of persons injured in a given type of accident who make liability claims (%)
All accidents	10
Motor vehicle	44
On the job	7
Other	3

Recovery Rates

The average percentage of economic losses recovered by persons with nonfatal injuries is given in Table 3. Overall, persons with nonfatal injuries can expect to recover approximately 62% of their economic losses. The recovery rate is higher for direct costs (75%) than for earnings losses (34%) [1].

Efficiency of Compensation Systems

The efficiency of the different compensation systems varies widely, as shown in Table 4. In the tort system, only 46 cents of each dollar spent on the system goes toward compensating victims [13]. In contrast, in public insurance programs, a much higher fraction of each dollar goes toward compensating victims.

The following section gives a more detailed discussion of the compensation provided by some representative insurance programs.

Examples of Insurance Compensation Programs

Private Accident Insurance

Accidental death and dismemberment policies provided by the private insurance market vary widely. An example of a schedule of benefits provided by such policies is given in Table 5. These policies make only crude assessments of the relative values of different types of injuries.

Workers' Compensation

Workers' compensation is an insurance plan provided by employers as per US law. It is a no-fault system, which pays employees for job-related injuries, disabilities, or death. Workers' compensation was intended to reduce the need for litigation, as well as the need to prove fault. In the majority of states, workers' compensation is provided solely by private insurance companies, but some states have a state fund or state-owned monopolies.

Workers' compensation provides compensation for both medical expenses and earnings losses. Benefits for disability vary across states, but are typically two-thirds of the worker's wages, with set minimum and maximum amounts per week. Some states also limit the duration of benefits. Replacement rates below 100% are meant to encourage employees to return to work, as well as to reflect the fact that these benefits, unlike earnings, are nontaxable.

Death benefits also vary from state to state. Benefits to dependants are typically two-thirds of the worker's wages, with set minimum and maximum amounts per week.

Table 3 Recovery rate for different types of losses associated with injuries in the United States

Category of loss	Specific type of loss	Recovery rate (average percentage compensated from all sources combined) (%)
Economic loss	Total direct and work loss	62
Direct costs	Total direct	75
	Medical treatment	84
	Other direct costs	10
Work loss	Total work loss	34
	Short term	66
	Long term	20

Table 4 Efficiency of different methods of compensation in the United States [14]

Method of compensation	Percentage of dollars spent on system that goes toward compensating victims (remainder goes to attorney fees and other costs) (%)
Tort system	46
Workers' compensation	80
Vaccine Injury Compensation Program	85

Table 5 Example of schedule of benefits provided by private accidental death and dismemberment policies. Actual benefits vary by policy

Loss	Percentage of principal benefit (%)
Death	100
Loss of use of one limb	50
Loss of use of two limbs	75
Loss of sight of both eyes	100
Loss of hearing of both ears	50
Loss of speech	50

National Vaccine Injury Compensation Program

The National Vaccine Injury Compensation Program is an example of a public insurance program. Created by the National Vaccine Injury Act of 1986, the program was intended to “ensure an adequate supply of vaccines, stabilize vaccine costs, and establish and maintain an accessible and efficient forum for individuals found to be injured by certain vaccines.” The program is a no-fault alternative to the tort system. Claims are decided by the US Court of Federal Claims.

The program provides compensation for medical costs, custodial care, rehabilitation costs, and other direct expenses associated with vaccine-related injuries. In addition, reimbursement is given for lost earnings, and up to \$250 000 may be awarded for pain and suffering. Over the history of the program, persons judged to have vaccine-related injuries have received an average compensation of \$824 000 per

person. For deceased victims, up to \$250 000 may be given as a death benefit to the estate [15].

Insurance versus Liability Compensation

Advantages of compensation from public insurance or a person's private insurance are speed and ease of reimbursement, as well as low transaction costs (see **Pricing of Life Insurance Liabilities**). However, such programs typically do not compensate fully for economic losses (in particular, earnings losses tend to be less than fully compensated) and often do not provide compensation for noneconomic losses. Thus, if a person feels that his/her injury is the resultant of another party's fault, he/she might make a liability claim and possibly turn to the tort system in an attempt to receive more comprehensive compensation. The tort system is discussed in the next section.

The Tort System

Overview of the Tort System

A tort is a civil wrong (as opposed to a criminal wrong) that results in personal or economic harm to another person and is recognized by law as grounds for a lawsuit. The aims of the tort system are generally agreed to be compensation (making the victim “whole”), deterrence (creating disincentives for putting others at risk), and justice (compelling the injurer to pay for the losses he/she has caused).

There are three general categories of torts: intentional torts (e.g., intentional battery), negligent torts (e.g., causing a motor vehicle accident by disobeying traffic laws), and strict liability torts (e.g., making or selling a defective product). US tort law is based primarily on common law, in which rules are developed on a case-by-case basis by judges, as opposed to statutory law, which is created by legislatures [16].

Statistics about the Tort System

The US tort system is largely a state system. Approximately 95% of tort lawsuits are filed in state courts, with the remaining 5% filed in federal courts. Most tort lawsuits are settled or dropped before a verdict is reached. Study of such cases is difficult since the details of settlements are usually private [14].

Of tort cases filed in state courts, approximately 97% are terminated before a trial verdict is given. Of tort cases (both personal injury and other torts) that reached a verdict in state courts in the United States' largest 75 counties in 2001, plaintiffs won 52% of the time, with a median award of \$27 000 to plaintiff winners [17].

Of the tort cases filed in federal courts in fiscal 2002–2003, approximately 98% were terminated before a trial verdict was reached. Of the personal injury cases that reached a verdict, plaintiffs won 48% of the time, with a median award of \$181 000 to plaintiff winners [18].

For wrongful death cases in general, the median award to plaintiff winners is approximately \$900 000, according to Jury Verdict Research [19].

Although trial verdicts represent only a small minority of cases filed, they are important in setting a precedent and thereby affecting the incentive to settle for other litigants.

Overall, approximately \$205 billion in direct costs, or about 2% of the US gross domestic product (GDP), was spent on the US tort system in 2001; this works out to approximately \$720 per citizen. Of this, approximately \$95 billion went toward compensating victims, whereas the remaining \$110 billion was spent on transaction costs. Of the component that went toward compensating victims, approximately half of it was for economic loss and the remaining for pain and suffering [13].

How Compensation is Determined

In the US courts, the types of damages that may be awarded include economic damages, pain and suffering, and punitive damages.

Economic Damages. According to the Restatement (Second) of Torts, the objective of the economic component of compensation is to restore the victim to “a position substantially equivalent in a pecuniary way to that which he would have occupied had no tort been committed” [20]. To determine economic damages, the jury considers testimony from expert witnesses and other parties involved in the case and makes an assessment of the appropriate level of damages to award.

Pain and Suffering Damages. The Restatement (Second) of Torts states that noneconomic damages

are “intended to give to the injured person some pecuniary return for what he has suffered or is likely to suffer. There is no scale by which the detriment caused by suffering can be measured and hence there can be only a rough correspondence between the amount awarded as damages and the extent of the suffering” [20]. All states allow compensation for pain and suffering for injury cases, while only a few states allow such compensation for wrongful death cases [21].

In deciding pain and suffering awards, juries have wide discretion and little guidance from the courts. Since there is no general agreement on what losses should be measured, nor how they should be measured, the standard procedure is to leave it to the jury [20]. There is no institutional “memory” in the courts of damages that have been awarded in the past for different types of injuries (it is not permitted to instruct juries on patterns of awards for similar cases). Therefore, there tends to be significant variation in awards made, even for similar injuries and accidents.

Plaintiff attorneys have attempted various ways to advise juries of appropriate levels of pain and suffering damages. It is generally *not* permitted for plaintiff attorneys to ask juries to consider how much compensation they would require before the fact to accept the certainty of the injury that the victim suffered, nor can attorneys ask juries to consider the compensation they would require after the fact to accept the victim's pain and suffering. Some jurisdictions do allow the “per diem” method, whereby jurors consider the compensation appropriate for a small unit of time and then multiply by the plaintiff's life expectancy. Also, “day in the life” videos may sometimes be used [22].

After the damages have been decided by the jury, the court may adjust the award if it is found to be excessive or if it exceeds statutory caps.

It is interesting to note that in England, personal injury cases are almost always tried by a judge because it is considered inappropriate for juries to be asked to assess compensatory damages [22].

Among law and economics scholars, there is a debate about “optimal” damages for pain and suffering. From a deterrence perspective, it is argued that defendants should bear the full cost of the injuries they have caused, however this “full cost” is determined. On the other hand, from a pure compensation perspective, the argument has been made that pain and suffering damages should be equivalent to the insurance coverage a rational and

informed individual would have purchased on the open market, if such coverage existed. Even if one agrees with this “insurance” argument, it is very difficult to ascertain how much coverage individuals would demand and pay for in such a hypothetical scenario [22].

Punitive Damages. In addition to compensatory damages, punitive damages may be awarded to punish and deter egregious behavior. The Restatement (Second) of Torts states that punitive damages are designed to “punish (the defendant) for his outrageous conduct and to deter him and others like him from similar conduct in the future” [23].

Because the purpose of punitive damages is to punish defendants rather than compensate victims, there is a controversy over who should receive punitive damage payments. Typically, plaintiffs receive any punitive damages awarded, although eight states (Alaska, Georgia, Illinois, Indiana, Iowa, Missouri, Oregon, and Utah) mandate split-recovery, whereby the plaintiff and the state split punitive damage awards between themselves [23].

Studies of Jury Awards

Various studies of jury award data have been carried out to assess what factors are correlated with higher awards and whether such awards are as arbitrary as critics contend. These studies have found that as much as half of the observed variation in awards can be explained by regression models, indicating that compensation of personal injuries is not as haphazard as sometimes perceived [21, 24].

In a study of personal injury cases from Florida and Kansas City between 1973 and 1987, cases were categorized by degree of injury severity on a nine-point scale. It was found that injury severity was the best single predictor of the amount of awards, explaining approximately 40% of the award variance. However, within each severity category, there was an enormous range of award values. For the most severe category, awards ranged from approximately \$150 000 to \$18 000 000. This calls into question the horizontal equity of the system, since injuries of similar severities may result in vastly different damage awards [25].

A study of nonfatal drunk driving injury cases between 1980 and 1990 found that juries placed a

value of approximately \$2.3 million on total impairment, a value of the same order of magnitude as VSL estimates from revealed preferences studies. This research also found that more weight was given to disabilities that were obvious to observers. In line with human capital theory, juries appeared to take earnings potential into account, providing the greatest awards to people between the ages of 30 and 45. In addition, awards were found to be higher when the defendant had deep pockets. In contrast, awards were found to be lower for plaintiffs perceived to be irresponsible (for example, plaintiffs who were impaired at the time of the accident) [21].

A study of permanent injuries in birth-related and emergency room cases found that compensation tended to fall short of the full economic cost of injuries. In particular, large losses were under-compensated relative to smaller ones – a percentage point increase in loss was found to raise compensation by far less than a percentage point [26]. The next section discusses how life and limb are valued in other contexts.

Valuing Life and Limb in Other Contexts

Value of Life for Setting Government Regulations

There is general consensus that, in principle, the proper way to value a statistical life when setting government regulations that affect health and safety is by WTP [9]. (In practice, however, WTP estimates based on survey data may reflect political attitudes, cues in the framing of questions or of response options, perceptions about legitimacy and fairness, and other factors that go beyond purely economic evaluation.) For more than 20 years, US federal agencies have used labor market estimates of the value of life to do cost–benefit analysis of health, safety, and environmental regulations [27].

As shown in Table 6, the VSL used by government agencies in setting regulations varies from approximately \$1 million to \$10 million, with average values clustering in the \$3 million to \$6 million range. This matches well with VSL estimates derived from economic studies.

Value of Life for Health Care Spending

In the area of health care, it is becoming increasingly common to evaluate the cost-effectiveness of

Table 6 Value of a statistical life (VSL) used by US federal agencies [4, 19, 28]

US federal agency	VSL (\$millions)	Year
Environmental Protection Agency (EPA)	6.3 (range from 1 to 10)	2004
Food and Drug Administration (FDA)	5.5	1996
Consumer Product Safety Commission (CPSC)	5.0	2000
Department of Transportation (DOT)	3.0	2002
Federal Aviation Administration (FAA)	3.0	1996
Food Safety Inspection Service, US Department of Agriculture (USDA)	1.9	1996
Average payout of the September 11th Victim Compensation Fund	1.8 (range from 0.25 to 7)	2003

medical interventions. In particular, countries with nationalized health care take the cost-effectiveness of different health care interventions into consideration when determining how to allocate limited resources.

To compare different medical interventions that may have disparate impacts on quality and/or length of life, a common unit is required. A unit that is often used is the quality-adjusted life year (QALY), which represents one year of perfect health. A year of life in a disabled or diseased state has a value between zero and one QALY, depending on the quality of life in that state. Each medical intervention can be assigned a cost per QALY, and the cost-effectiveness of different interventions can thereby be compared. Other units used for this type of comparison include the disability-adjusted life year (DALY) and health-adjusted life expectancy (HALE).

In the United Kingdom, the National Institute for Clinical Excellence (NICE) is an independent organization that provides national guidance on the adoption of new medical interventions. NICE evaluates the cost-effectiveness of pharmaceuticals and other medical treatments, using an implicit threshold of approximately £30 000 per QALY when deciding whether or not to recommend an intervention. (In general, NICE tends to recommend interventions that cost less than £30 000 per QALY, whereas it does not typically recommend interventions that cost more than this [29, 30].)

In the United States, there is no accepted cost per QALY threshold. Indeed, Medicare explicitly rejects cost-effectiveness as a criterion for approving new medical technologies. However, interventions are generally considered to be good value if they cost less than \$50 000 to \$100 000 per QALY. The \$50 000 per QALY benchmark arises from Medicare's decision in the 1970s to cover dialysis for chronic renal failure

patients, a treatment with a cost-effectiveness ratio of approximately \$50 000 per QALY [31]. Studies using WTP and revealed preferences approaches suggest that the public values a QALY even higher than this – over \$200 000 [32].

To translate, at least very roughly, between QALYs and VSL, one could make the assumption that the average value of a person's remaining years of life is about 40 QALYs (approximately half the US life expectancy). In this case, a cost per QALY between \$50 000 and \$200 000 translates to a VSL of roughly \$1 million to \$8 million, depending on the discount rate used to calculate present value. This is in line with the range of VSLs used by government agencies in setting regulations.

Conclusion

Overall, there are trade-offs to be made in any type of compensation system. No-fault systems, such as private and public insurance, tend to be efficient, with low transaction costs. However, such systems do not accomplish other objectives such as deterrence and justice, which the tort system attempts to achieve.

Criticisms of the US tort system revolve around its high transaction costs, as well as the unpredictability and inconsistency of awards. Various proposals have been put forth to reform the tort system. Some argue that pain and suffering awards should be capped, but such caps would only come into play for the most severe injuries, while having little effect on overvaluation of minor injuries. Others propose that damages should be calculated *via* schedules, matrices, scenarios, or multipliers. However, such systems do not address the fundamental question of how damages should be valued in the first place. On that question, there is significant ongoing debate, both

on the value of a life overall and on the value of the loss of enjoyment of life associated with different types of injuries.

Competing Risks

General Description of Competing Risk

Competing risks are generally evaluated by comparing the predicted time to failure or time to event for the risks being considered. Failure could represent breakage of a specified part of an automobile, death from a specified cause such as lung cancer, or failure of a specified component of a mechanical or electrical system, or the event could be transition from unemployment to employment or time to place an order on a stock exchange. We consider the situation in which there could be several potential causes of death, but only one actual cause per person, or mechanical or electrical systems without repair processes in which the failure of one of several key components could cause the system to fail. In this case, it is of interest to estimate what would happen to the remaining risk if one or more causes of failure could be eliminated. More areas of interest include study of the relationships between type of failure and covariates, study of systems in which multiple failures can be expressed, and study of the relationships between different failure types. It should be noted that the common situation of right censoring, “i.e., for some members of the sample group it is only known that the failure or event has not occurred prior to the observation time, is itself a form of competing risk.”

Mathematical Formulation

Here we describe the competing-risk problem in the standard formulation of random variables. This allows a precise description of the problem. Let $R_1, R_2, \dots, R_n$ represent the risk of failure of n different components, or n distinct causes of death. Let T_i be a random variable representing the time to failure for risk R_i . Further, let F_i be the cumulative probability distribution function of the time to failure, i.e., $F_{T_i}(t) = \text{probability}\{T_i \leq t\}$. In this formulation, the n different risks compete with one another in the sense that the failure is attributed to the risk for which the failure occurs first. In other words, the time to failure, T , of the entire process is $\min\{T_1, T_2, \dots, T_n\}$.

In the case of electrical processes, or other systems in which it is possible to build a system of independent parallel and/or serial circuits, the individual risks

are likely to be statistically independent; it may even be possible to gather data for each of the risks and estimate each of the F_i . In this case, the probability distribution of time for failure for the entire system is easily derived from probability calculus as

$$F_T(t) = \text{Probability}\{T \leq t\} = \prod_{j=1}^n F_{T_j}(t) \quad (1)$$

For the case of independent identically distributed risks, $F_T(t) = \{F_{T_1}(t)\}^n$.

If the times to failure for the individual risks are not mutually independent, then to determine the probability distribution of time to failure for the entire system, it is necessary to know the joint probability distribution of the n risks, i.e.,

$$F_{T_1, T_2, \dots, T_n}(t_1, t_2, \dots, t_n) = \text{Probability}\{T_1 \leq t_1, T_2 \leq t_2, \dots, T_n \leq t_n\} \quad (2)$$

In many practical problems, all available data consist of observations for which all of the competing risks apply. And furthermore, only the pair (T, J) is observable where T is the failure time of the system, i.e., $\min\{T_1, T_2, \dots, T_n\}$ and J is the type of failure. Without assumptions about the form of the joint probability distribution of times to failure, it may not be possible to estimate even the marginal probability distribution function, much less the complete joint probability distribution. One method for dealing with the dependence problem is to assume a known form for the dependence relationship between the failure types. The dependence relationship can be specified by means of the copula function, C (see **Copulas and Other Measures of Dependency**); for example, the joint probability distribution can be expressed as

$$F_{T_1, T_2, \dots, T_n}(t_1, t_2, \dots, t_n) = C[F_{T_1}(t_1), F_{T_2}(t_2), \dots, F_{T_n}(t_n)] \quad (3)$$

where $F_{T_1}(t_1), F_{T_2}(t_2), \dots, F_{T_n}(t_n)$ are the marginal probability distributions.

Zheng and Klein [1] developed an estimator for the marginal distribution based upon using a known (or assumed) form for the copula. Their method reduces to the Kaplan–Meier estimator if the copula is the independence copula, $C(y_1, y_2, \dots, y_n) = y_1^* y_2^* \dots y_n^*$. The use of a copula to specify the range of possible dependence can be used to estimate upper

and lower bounds for the marginal probability distributions, F_{T_i} . Zheng and Klein [1] showed that if a good estimate of dependence between T_i as measured by Kendall's τ is available, then the estimate of the marginal probability distribution functions is not sensitive to the exact form of the copula as long as it is consistent with the "known" value of τ . Of course, τ must be known *a priori*; it cannot be estimated from the data when only the pairs (T, J) are observed.

It is frequently useful to describe the failure time process through the hazard function (see **Hazard and Hazard Ratio**), h_T , rather than through the probability distribution, F_T . The hazard function describes the current risk for the population that has survived up to the current time and often has a simpler mathematical form. The hazard function at time t is the conditional probability of failure, conditional upon survival up to time t .

Specifically,

$$h_T(t) = \lim_{\Delta \rightarrow 0} \frac{1}{\Delta} [F_T(t + \Delta) - F_T(t)] / F_T(t) \quad (4)$$

In the case of competing risks and continuous-time measurement, it is typically assumed that at any given instant, t , only one failure can occur. In this case, the hazard function for the combined risk is the sum of the hazard functions for each of the failure types, that is,

$$h_T(t) = \sum_{j=1}^n h_{T_j}(t) \quad (5)$$

where $h_{T_j}(t)$ is the hazard function for failure type j .

Proportional Risk Models

The proportional risk model introduced by Cox [2] has been used to generalize the competing-risk framework beyond independent identically distributed observations.

In this formulation, the observed quantities are the triples (T, J, X) , where T is the time to failure, J is the failure type, and X is a vector of covariates, i.e., a set of variables that can be measured for each individual and are thought to be related to the risk of failure.

In the proportional risk model the hazard function for failure type j is expressed as

$$h_{T_j}(t) = \lambda_0(t) \exp(\gamma_j + X\beta_j) \quad (6)$$

where γ_j and β_j are the parameters to be estimated from the data.

The method of partial likelihood, which conditions upon the observed failure times, can then be used to estimate the parameters γ_j and β_j , while $\lambda_0(t)$ is an unspecified function of time.

Notice that, in this formulation, the case-specific hazard functions must be proportional to one another, and that conditional upon the value of the covariate, X , the time to failure, T , and the failure type, J , are statistically independent.

Frailty Models

Another generalization beyond independent identically distributed risk is the frailty model, frequently used in economic and financial applications as well as in epidemiological applications.

Variation between individuals in the population is modeled through an unobservable frailty variable, W , which represents the effect of unobserved or unknown covariate or other natural variation in the population. Conditional upon the value of the frailty, the time to failure (or event) is assumed to follow a proportional hazards framework. The hazard function for event type j , in the presence of other events, for the i th observation is

$$h_{T_{ji}}(t) = W_{ji} \lambda_0(t) \exp(X_i \beta_j) \quad (7)$$

where, T_{ji} is the time to event type j for observation i , W_{ji} is the frailty for event type j for observation i , $\lambda_0(t)$ is the baseline hazard function, X_i is the observed covariate for observation i , and β_j is the parameter to be estimated from the data. Typically the frailty variable, W , is considered to be an unobserved random variable in the population under study. In order for this model to be identifiable, it is necessary to use a parametric framework for the baseline hazard and for the frailty. Typical models include Weibull, Gompertz, exponential, and piecewise-linear. Dependence between the event times for the competing risk can be handled by assuming a dependence structure for the multivariate frailty variable $(W_{1i}, W_{2i}, \dots, W_{ni})$.

Statistical Methods for Estimating Competing Risk

Independent Competing Risks and Censoring

Statistical estimation methods for time to event data include completely nonparametric methods such as lifetable analysis and Kaplan–Meier estimates, semi-parametric methods such as the Cox proportional hazard models, and completely parametric methods. All of these methodologies are suitable for the case of independent competing risks. The statistical estimation methods for each of these methods include provision for handling censored data. An observation is right censored if it is only known that the time to event is at least as long as the observed time. This situation occurs naturally in most situations. Examples include the following: (a) patients are followed until a date when the data collection part of the study ends; survival time is censored for those patients still alive at the close of the study; (b) patients are lost to follow-up; the observed time is the time of last contact. As another example, a product is stress tested until failure or for 48 h; products that do not fail within the 48 h period are right censored.

All of the statistical methods for handling censored data rely upon the assumption of random censoring, that is, stochastic independence between time to event and censor time. This condition is automatically satisfied when the only censoring is end of the study. In this case, the time to censoring is fixed and consequently independent of the time to failure.

It is clear that it would be impossible to learn anything about the distribution of time to failure if the censoring mechanism systematically censored individuals from the study if they appeared to be at high (or low) risk of failure. In the case of loss to follow-up, the independence condition is not necessarily met; some additional testing or tracing of individuals lost to follow-up is needed to verify the independence assumption.

Mathematically, censoring is equivalent to a competing risk. The observed data consist of a triple (T, J, X) , where T is the observed time, J is an indicator of whether censored or not, and X is a vector of covariates. If no covariates are observed, X can be considered as a constant.

Generalizing this to the competing-risk situation, we see that by sequentially treating each failure type of the relevant failure mechanism and all other failure

types as censoring mechanisms, all of the standard statistical methods for independent censoring can be used with competing risks as long as the assumption of independence between hazards is satisfied.

Lunn and McNeil [3] noticed that with competing risks, each failure time represents an uncensored failure time for the type of failure that was observed and a censored failure time for all other types of failure. They developed an analysis method that treats failure type as a covariate in the Cox model and is sometimes more powerful than the more common method of treating each risk separately and classifying other types of failures as censored observations.

Dependent Competing Risks

The situation is substantially complicated if the competing risks (or censoring mechanisms) are not independent. As can be seen in the previous discussion, the distribution of time to failure for dependent competing risk is not identifiable in the absence of some assumption about the nature of the dependence.

Wong [4] introduced the concept of susceptibility to model-dependent competing risks in a lifetable analysis. Let q_{ji} be the probability of failure from cause j in interval i in the presence of all competing risks of failure, and let q_{jik} be the probability of failure from cause j in interval i for units that (formerly) failed of cause k , if cause k was eliminated as a type of failure. In the Wong model $q^{ijk} = S_{jki}^* q_{ji}$, where S_{jki} is the relative susceptibility of failure from cause j for units that failed from cause k . If S_{jki} is greater than 1, then if cause k could be eliminated, units that (formerly) would have failed from cause k would be more likely to fail from cause j than the rest of the population; if $S_{jki} = 1$, then causes j and k are independent; if S_{jki} is less than 1, then if cause k could be eliminated, units that (formerly) would have failed from cause k would be less likely to fail from cause j than the rest of the population. The susceptibility is not directly estimable from lifetable data that only records actual cause of failure. Wong suggests using auxiliary information, such as contributing cause of death, to produce external estimates of the susceptibilities. Wong demonstrates a lifetable calculus for estimating the probability of failure from cause j , when cause k has been eliminated from the population.

A two-stage nonparametric method for estimating the cumulative distribution of cause-specific time to failure is described in Kabfleisch and Prentice [5] and illustrated by Satagopan *et al.* [6]. The Kaplan–Meier method is used to estimate the overall failure rate for all types of failure combined. In the second stage, the failure rate is partitioned into failure classes by computing the cause-specific failure rate in each interval given survival up to that interval. Let t_{ji} be the i th failure from cause j . As in the Kaplan–Meier method, the probability of cause-specific failure at time t_{ji} is the product of the all-cause probability of survival up to time t_{ji} and the cause-specific probability of failure in the interval t_{ji-1} to t_{ji} . The causes of failure need not be independent in this method.

The bivariate frailty model is one form of dependence of competing risks that has found application in the analysis of data from twin studies and other studies of genetic markers. Not only is it necessary to assume that the dependence can be expressed through the multiplication of the unobserved frailty variable upon the underlying hazard function, and that lifespan (or time to event) is conditionally independent given the frailty, but also a parametric form for the frailty variable must be assumed to allow estimation of the distribution of time to event.

The hazard function for the j th risk and the i th observation is $h_{T_{ji}}(t) = W_{ji}\lambda_0(t)\exp(X_i\beta_j)$ in a frailty model. For some combinations of distributions for the baseline hazard $\lambda_0(t)$ and the frailty variable W_{ji} , the frailty term can be integrated from the likelihood function and maximum-likelihood estimates can be calculated. This is the case when $\lambda_0(t) = A\exp(Bt)$ (Gompertz) and the W_{ji} are gamma functions [7]. In other cases, e.g., when the W_{ji} follow a lognormal distribution, explicit representation of the likelihood function is not possible. Estimation methods include penalized partial likelihood [8], a modification of the EM algorithm [9, 10], and Bayesian analysis with Gibbs sampling [7].

The multitude of ways in which competing risk can depend upon one another means that there is no simple general way to model a dependent competing-risk process. The frailty models are a useful way of modeling dependent competing risks by choosing a well-behaved probability distribution for the underlying hazard functions and for the distribution of individual susceptibility or frailty.

Applications of Competing Risk

Engineering

Reliability. Consider a system that contains n components, and failure of any one of which will cause the system to fail (sequential system). Assume that components will fail independently of one another. What is the reliability (probability that the system has not failed) at time τ ?

Let T_j represent the random time to failure of component j , and F_{T_j} be the probability distribution function of T_j . Then $1 - F_{T_j}(\tau)$ is the probability that component j does not fail prior to time τ . The reliability of the system at time τ is the probability that no components have failed by time τ ; and this is given by

$$1 - F_T(\tau) = \text{Probability}\{T > \tau\} = \prod_{j=1}^n [1 - F_{T_j}(\tau)] \quad (8)$$

A second system consists of n components. If any one component continues to work the system will work (parallel system). How many parallel components are needed for a specified reliability at time τ ? Assuming identical components, let F_{T_0} be the probability distribution function of the time to failure for each component and $R(\tau)$ be the required reliability to time τ . Then the number of components required for $R(\tau)$ is the solution to the following equation:

$$R(\tau) = \text{Probability}\{T > \tau\} = 1 - F_{T_0}(\tau)^n \quad (9)$$

$$\text{Or } n = \frac{\log[1 - R(\tau)]}{\log[F_{T_0}(\tau)]} \quad (10)$$

Weibull Models. In some situations multiple causes of failure, i.e., competing risks, may exist, but the cause of failure is not observable or has not been investigated for the failed units and only the time to failure, or censoring, is known. The Weibull distribution with probability distribution function $F(t) = 1 - \exp[-(t/\alpha)^\beta]$ is often used to model failure time in this context.

A plot of the log of the empirical cumulative distribution function of failures, $F(t)$, against time is used to judge whether the observed failure process has only one failure type or multiple failure

Figure 1 Plot for Weibull failure time with single failure type “W/mle: with maximum likelihood estimates”; “n/s: n is the total number of units”; “s is the number of censored units”

types. Figure 1 shows a plot that indicates that a single failure type Weibull distribution fits the data. Figure 2 shows the corresponding plot when there are two failure types. The sharp change in the slope of plot of $\log F(t)$ versus time is the indication of two failure types in this example. The WeibullSmith program for Weibull analysis contains algorithms to fit competing-risk models with an unspecified number of causes of failure, each of which follows a Weibull distribution. Note that, for the failure types to be distinguishable, they must have substantial differences in the parameters of the Weibull distributions. Two or more failure types that each have the same distribution of time to failure could not be distinguished without the observation of the failure type.

Medicine

Use of the mathematics of competing risk in medicine go back to Daniel Bernoulli (1766) and his analysis of mortality due to smallpox and normal mortality [11]. Here, a two state model was used. Individuals could be in a normal state with normal force of mortality or in a smallpox state in which individuals would

either die very quickly or recover and no longer be susceptible to smallpox.

The Cox proportional risk model and partial likelihood method as well as the Kaplan–Meier method [12] are now widely used in epidemiology and medicine. A few recent articles that give the flavor of the wide use of competing-risk ideas in medicine are [13–15].

The Kaplan–Meier method is considered suboptimal by some for use in short-term situations such as waiting lists for transplant or death during hospitalization. Some researchers [16] recommend logistic regression or other methods unrelated to survival time, while others [4, 17] recommend nonparametric lifetable type methods or Poisson regression methods.

Economics and Finance

Competing-risk models in general and the Cox proportional hazards model in particular are now widely used in economic and financial applications. The publication of Han and Hausman [18] is cited in at least 50 publications. An [19] credits Suiyoshi and McCall for introducing competing-risk methods to economic applications.

Figure 2 Plot for Weibull failure times with two failure modes

Applications of competing risk include analysis of length of unemployment, time to graduation or drop out from college, length of time to execution or cancellations of orders in financial markets, time to default or prepayment of mortgages and acquisitions of banking institutions – in short, any situation in which there are multiple reasons for transitioning from one state to another.

Competing Risks in Reliability

Competing risks models (*see* **Repair, Inspection, and Replacement Models; Absolute Risk Reduction**) are a class of models in reliability that can be used to analyze operational field data. They assume that different failure risks and maintenance events are in competition with one another to be the cause of the system being taken out of service and that these risks censor each other, that is, only the first occurring cause is observed. Particularly significant for many applications is the fact that maintenance masks the failure event that would have happened in the future. Competing risk models implicitly assume the renewal property (*see* **Mathematics of Risk and Reliability: A Select History**) to hold. In many situations, the cost of critical failures in a system is so large that it is necessary, when components are repaired or maintained, to have a policy that ensures that they are restored to a state that is as good as new. Thus, the event times can be modeled as a renewal process with interevent times $Y_1, Y_2, \dots$, which are modeled as independent and identically distributed random variables. Raw field data for reliability is frequently found in maintenance and repair logs. Generic reliability databases make implicit use of competing risk models to convert this raw field data into information about system failure rates. Examples of these include the Centre for Chemical Process Safety (CCPS) [1] and the European Industry Reliability Database (EIREDA) [2]. A discussion of how such databases are built and their use in competing risks problems can be found in [3]. It is because of the censoring (*see* **Detection Limits; Recurrent Event Data; Lifetime Models and Risk Assessment; Hazard and Hazard Ratio**) feature of competing risk models that problems arise when trying to identify marginal distributions for the time to failure. From a purely statistical point of view it is not possible, without making nontestable assumptions, to identify the underlying marginal distributions for times to failure (mode) or time to maintenance. This non-identifiability problem can only be surmounted by making assumptions about the underlying dependencies between the competing risks variables, requiring a deeper understanding of the maintenance policies in place, which leads to more qualitative forms of model

validation. For a more general review of competing risks, which includes more general applications to survival analysis, see Crowder's recent book [4].

Main Theoretical Ideas

For simplicity, let us consider one failure cause and one preventive maintenance action. Let X denote the time to the next removal from service due to failure and let Z denote the time to the next preventative maintenance. For simplicity, we shall assume that X and Z cannot occur at the same time. In practice we can only observe $\min(X, Z)$, the smallest of X and Z , and we can also observe which variable it is $I_{\{X < Z\}}$ where

$$I_{\{X < Z\}} = \begin{cases} 1 & \text{if } X < Z \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

It would be very useful to know the distribution function of X to ascertain how changes in the maintenance policy will impact on the reliability of the system. However, we can only observe the subdistribution function

$$F_X^*(t) = P\{X \leq t, X < Z\} \quad (2)$$

This function increases to $P\{X < Z\}$ as t tends to infinity. An equivalent function that is often of interest is the subsurvival function

$$S_X^*(t) = P\{X > t, X < Z\} = P\{X < Z\} - F_X^*(t) \quad (3)$$

The normalized subsurvival function $S_X^*(t)/S_X^*(0)$ is equal to 1 at $t = 0$. Similar functions are also defined for Z as well. Another important quantity is

$$\Phi(t) = P\{Z < X | Z > t, X > t\} \quad (4)$$

the probability that, at time t since the component went into service, the next event will be Z . The functions $F_X^*, F_Z^*, S_X^*, S_Z^*$, and Φ can be directly estimated from observable data. These functions can be useful when selecting models.

Nonidentifiability Problem

Historically, assumptions about independence of X and Z were made in competing risks to be able

to identify marginal distributions from the data. However, Tsiatis [5] showed that this assumption was not testable using the data by showing that many joint distributions (including an independent model) could share the same subdistribution functions. This feature of competing risk models is frequently referred to as the nonidentifiability problem. Accepting the problem of nonidentifiability, Peterson [6] was able to show that the marginal distribution functions of X and Z are bounded pointwise in the following manner

$$F_X^*(t) \leq F_X(t) \leq P\{\min(X, Z) \leq t\} \quad (5)$$

Crowder [7] was able to demonstrate functional bounds which showed that the marginal distribution function $F_X(t)$ minus Peterson lower bound is a nondecreasing function in t . Bedford and Meilijson [8] were able to improve these results while demonstrating a simple geometric construction. The Peterson bounds are illustrated in Figure 1. This shows the upper Peterson bound, which is simply the distribution function for $Y = \min(X, Z)$, the lower Peterson bound (which is simply the subdistribution function for X), and two possible distribution functions for X (that is, marginal distribution functions for X to a joint distribution for X and Z that has the given subdistribution functions). It also shows an exponential distribution function that does not satisfy

the Peterson bounds, and therefore can be excluded as a possible marginal for X . In this particular case, no exponential distribution will fit into the Peterson bounds.

Although, in general, we cannot identify marginal distributions from competing risk data, it may be reasonable to make assumptions that restrict attention to a subclass within which we can identify marginal distributions.

Independent Model

If X and Z are independent, nonatomic, and share essential suprema, then it has been shown [9–11] that their marginal distributions can be uniquely identified. If we are given a pair of subdistribution functions, then we can always assume independence and calculate the unique marginal distributions. However, it is possible that one of the random variables will have an atom at infinity [12]. This means that we can always identify marginal distributions if we assume independence, but that we need to justify this assumption outside of the competing risks data. It was shown [13] that any other model involving dependence between X and Z would give a higher estimate of the failure rate than the independent model. Indeed, considering the class of all models in which the failure rate is constant, the interval containing these

Figure 1 Illustration of the Peterson bounds

failure rates has a minimum value equal to the failure rate associated with the independent model.

Other Competing Risk Models

As discussed above, without making some assumptions, which cannot be validated statistically, it is not possible to identify underlying marginal distributions. However, a number of models have been proposed, which try to circumvent this problem usually by hypothesizing an engineering scenario within which the data has been generated. This has given rise to a number of different models.

Dependent Copula Model

The first model is a simple one that allows us to consider the effect of dependence on the estimate of the marginal. Copulas (*see Credit Risk Models; Default Correlation; Extreme Value Theory in Finance; Copulas and Other Measures of Dependency*) can be used to model the dependency between X and Z , and it was shown in [14] that a generalization of the Kaplan–Meier (K–M) (*see Detection Limits; Individual Risk Models*) estimator could be defined that gives a consistent estimator on the basis of an

assumption about the underlying copula of (X, Z) . By selecting a family of copulas, parameterized by the (rank) correlation of X and Z , we can perform a sensitivity analysis to see how the dependence parameter affects the results. For example, [15] used a family of copulas to show how sensitive optimum maintenance costs are to the choice of an underlying model for interpreting the data. Figure 2 shows upper and lower Peterson bounds for the marginal distribution of X , the actual analytical marginal used, and the K–M estimate for the marginal of X . The latter estimator, of course, makes the assumption that X and Z are independent when, in fact, in this simulation, they had a positive rank correlation. It has been observed that the assumption of independence gives a more optimistic view of the marginal distribution for X than an assumption of positive dependence, and this can be seen from the figure, where the K–M estimator lies to the right of the true distribution. All quantiles for the K–M estimator are higher than the corresponding true quantile.

Delay Time Model

The delay time model (*see Repair, Inspection, and Replacement Models*) has been used a lot

Figure 2 Illustration of the K–M estimator

in maintenance modeling [16]. It assumes that a degradation signal is given by a component, say at time U , after which there is another period, say V , until failure. The failure time is thus, $X = U + V$. To make a competing risk variant of this model, we can assume that a maintainer is walking round the plant, and if he happens to observe the equipment in its degraded state, then he will maintain it. Hence, the time to preventive maintenance is $Z = U + W$ where W is exponentially distributed. It is assumed that U , V , and W are mutually independent. A special case of this model discussed in [17] shows that if we assume that these variables are exponentially distributed, then $\Phi(t)$ is constant and a simple formula exists for estimating the model parameters.

Alert Delay Model

This model, presented in [18], assumes that

$$Z = p + \varepsilon \quad (6)$$

$$X = pX + (1 - p)X \quad (7)$$

where X and ε are exponentially distributed and independent of each other, $p \in [0, 1]$. This looks similar to the delay time model except that pX and $(1 - p)X$ are not independent. pX represents the time in which the system issues a warning signal, and ε represents the delay needed to carry out the preventative maintenance.

Random Signs

This model, discussed in [19], assumes that the preventative maintenance is related to the failure time by

$$Z = X + \delta\varepsilon \quad (8)$$

where $\delta = \pm 1$ is independent of X , and ε is a strictly positive random quantity. The random signs model represents a policy of preventative maintenance where in order to maximize its effectiveness, such maintenance should only be carried out as close to the time of failure as possible. Whether or not such maintenance succeeds in repairing the system before failure is represented by δ .

LBL Model

This model is a variation of the random signs model presented in [20]. The model assumes that

$$P\{Y \leq y | Y < X, X = x\} = \frac{H(y)}{H(x)} \quad 0 \leq y \leq x \quad (9)$$

$$H(x) = \int_0^x r_X(u) du \quad (10)$$

This means that the likelihood of an early intervention of preventative maintenance on a system is proportional to the unconditional failure intensity of the system.

Repair Alert Model

This model is presented in [21] and is a special case of the random signs model, which imposes additional structure by specifying a general function $G(t)$ in place of $H(t)$. $G(t)$ reflects the alertness of the maintenance team. This model generalizes the LBL model, which takes $G(t)$ to be the failure rate function of X . One of the properties of this model is that $\Phi(t)$ is increasing.

Random Clipping

We assume that X is exponentially distributed and that there is a variable $Z = X - W$ where W is a strictly positive random variable, independent of X . Z represents the time till a warning signal is issued by the system in some way. It was shown in [22] that regardless of the distribution for W , $X - W$ has the same distribution as X . This means that these warnings can be used to estimate important properties such as the mean time before failure of the system.

Mixed Exponential Model

This is a special case of independent competing risk models, which assumes that X is modeled by a pair of exponentially distributed variables, while Z is also exponentially distributed and independent of X . A useful property described in [23] is that $\Phi(t)$ is continually increasing from the origin. The underlying interpretation of this model is that the data consists of two distinct subpopulations, but that the maintenance regime is the same for both.

Summary

The identifiability competing risk problem is one that arises naturally in analyzing reliability field data. Taking the lead from work survival analysis, it is common to assume that the censoring is independent. However, consideration of the engineering context suggests that this is unlikely to be a reasonable assumption in many cases. The Peterson bounds give best possible upper and lower bounds for the marginals, and these are generally very wide, and therefore, not useful in practice. A number of models have been constructed however, that are built on an explicit engineering scenario. These models can be validated on engineering grounds, and are identifiable, making them useful for the practical interpretation of reliability field data.

TIM BEDFORD, BABAKALLI ALKALI
AND RICHARD BURNHAM

Compliance with Treatment Allocation

Consider a male in his early 70s. From his previous experiences, he thinks that if he catches a cold or influenza, it is almost certainly going to lead to a potentially serious or, at least, very unpleasant bout of bronchitis. Would it be worth his while to get an influenza vaccination (a “flu jab”) each autumn? Would a flu jab reduce his risk of bronchitis or similar flu-related complications? He decides to search the Internet for information and finds the results of a randomized trial designed to answer this question. But how does he evaluate the results? The investigators randomly allocated half of the trial participants (people aged 65 or over who are registered with their family physician or general practitioner (GP)) to receive a letter from their GP encouraging them to attend their local health clinic to get a flu jab. The other half do not get the letter, but continue to receive any health checkups, advice and treatment as usual (TAU). Those allocated to receive the letter also, of course, get access to TAU; so the trial is evaluating the difference in outcomes for patients who receive TAU+ letter and those who get access to TAU alone. The letters were sent out at the beginning of October, and the primary outcome measure was whether the participant suffered from serious flu-related complications over the following 6 months.

The authors report an intention-to-treat (ITT) effect (see **Intent-to-Treat Principle**) indicating that sending out the letter reduces the proportion who get complications from 0.10 to 0.08 (i.e., a drop of 2%). The trial was large, so the difference was statistically significant, but to the man, the difference looks trivial. It may be an important difference from the point of view of public health (or the cost of care to the health services), but is this small reduction of any consequence to him personally? Looking at the trial results more closely, he now notices that only 30% of those participants who received the letter took up the offer and actually received a flu jab. And 10% of the participants in the other arm of the trial had a flu jab, even though they had not received the letter inviting them to get one. The ITT effect is the effect of sending out the letter. It does not estimate the effect of receiving the flu vaccine; or, if it is treated as such,

it is an estimate that can be quite severely biased (attenuated) by both the failure of those offered the vaccination to take up the offer and by the receipt of the flu jab in many of those not invited to attend the clinic for the vaccination. What is the scale of this attenuation? How can we adjust for it to get a better idea of the reduction in risk of flu-related complications if we go out and get vaccinated?

A naïve approach to the problem would simply compare the outcomes in those people who were vaccinated with those who were not (the “as-treated” estimator – see below). But here we would not necessarily be comparing the outcomes in people with similar prognoses. There would be confounding, leading to so-called selection biases: we would not be comparing like with like. Those people who turn down the offer of vaccination are likely to be fitter on average than those who comply with the offer. Those who turn down the offer of vaccination will, on average, have a better treatment-free prognosis. The reverse will be true for those who are vaccinated irrespective of the letter offering them vaccination. Those are the people who because of prior medical conditions, for example, are thought to have a poor treatment-free prognosis. If we were able to take measurements of baseline (prerandomization) covariates that were associated with the receipt of vaccination (i.e., compliance) and also had an influence on the outcome (i.e., confounders), then we could make appropriate adjustments to the as-treated estimate. In practice, however, there will always be unmeasured or hidden confounders. So, where do we go from here? The aim of the present article is to illustrate how one might allow for selection effects (hidden, confounding) to obtain valid estimate of the effects of treatment receipt in those who comply with their randomized allocation.

Randomized Encouragement Trials and Randomized Controlled Trials (RCTs) with Noncompliance with Allocated Treatments

The hypothetical influenza vaccine trial described above is an example of what has been termed a *randomized encouragement trial* (for a real example, see Hirano *et al.* [1]). Participants are encouraged to change their behavior in a particular way (or not, if they are allocated to the control condition), but there is little expectation on the part of the trial

investigators that participants will fully comply with the request, or that there will not be a substantial minority in the control condition who change their behavior in the required way without actually being asked (by the trial investigators, at least) to do so. Another example involves randomizing expectant mothers (who are also cigarette smokers) to receive advice to cut down on or completely stop smoking during pregnancy [2]. Many of the mothers may fail to reduce their smoking even though they have received encouragement to do so. On the other hand, many may cut down on their smoking whether or not they have received the advice suggesting that they should do so. Randomized encouragement to take part in cancer screening programs is another familiar example [3–5]. Again, adherence to the offer of screening will be far from complete but, on the other hand, there are always people who will ask for the examination in any case. Similar, if not identical, in design and purpose to the randomized encouragement trial is Zelen's *randomized consent* trial [6, 7]. Zelen's design might be applied to both screening trials and to conventional clinical (treatment) trials. Randomized consent designs were introduced by Zelen to improve recruitment to randomized trials. In a conventional trial, the investigators seek informed consent from the potential participants prior to randomization. In the randomized consent design the order is reversed:

“After the patient's eligibility is established, the patient is randomized to one of two groups. Patients randomized to A are approached for patient consent. They are asked if they are willing to receive therapy A for their disease. All potential risks, benefits, and treatment options are discussed. If the patient agrees, treatment A is given. If not, the patient receives treatment B or some other alternative treatment that the physician is willing to recommend. Similarly, those patients assigned to B are approached for consent with a comparable discussion.” [7, p. 646]

If, say, treatment A is an established form of care, and B is a novel untested alternative, a variant of the above design (the single consent design) is to seek consent only from those patients who have been randomized to treatment B. Patients allocated to A are receiving exactly the same care as they would have received if they were not part of the trial, so their agreement to participate is not sought. In this situation, patients allocated to receive A do not have access to B (they may not even be aware

of its existence). Such designs may be objected to on ethical grounds, and they are potentially quite controversial. The point of describing them here, however, is not to promote their use, but to illustrate how treatment switching might be a direct result of the choice of the trial design.

Although it is not always adequately reported, it is increasingly obvious that most conventional randomized clinical trials (*see Randomized Controlled Trials*) (i.e., ones in which informed consent is sought prior to randomization) are subject to noncompliance. Adherence to the offered treatment or management package is rarely complete. People fail to turn up for therapy (Bloom's “no shows” [8]) or they fail to take sufficient amounts (or even any) of their prescribed medication. Sometimes, they are switched to a treatment that is not mentioned in any of the arms of the trial (rescue medication or emergency surgery, for example). It is important, however, that this noncompliance to the allocated treatment protocol does not necessarily indicate “delinquent” behavior on the part of the patient. It is often quite legitimate and in the interests of the patient's health or even survival. The patient's physician is always free to vary or switch the patient's medication if he or she feels that it is in the interest of the patient. The patient may be withdrawn from the trial altogether or offered a treatment unrelated to those being compared in the trial. For this reason, nonjudgmental terms such as “nonadherence” or even the completely neutral “departures from randomization” [9] are increasingly used instead of the apparently more disapproving “noncompliance”. Here, we used the terms “noncompliance” and “nonadherence” interchangeably.

Matthews [10, pp. 116–117] illustrates the problem of treatment switches in a trial to compare surgical and medical treatments for angina (European Coronary Surgery Study Group [11]). Data on treatment actually received, together with 2-year mortality, are shown in Table 1. Here the switches are likely to have resulted from clinical decisions, rather than noncompliance on the part of the patients. For example, some of the patients allocated to receive surgery may have been too ill for the procedure to take place (Table 1 shows that this subgroup has the highest 2-year mortality). Creed *et al.* [12] describe what we will refer to as the *day care trial* to compare the effects of day and inpatient treatment of acute psychiatric illness. Randomization produced 93 inpatients and 94 day

Table 1 A surgical intervention trial with both noncompliance and contamination

	Allocated to surgical treatment ($z = 1$)		Allocated to medical treatment ($z = 0$)	
	Actually received surgical treatment ($t = 1$)	Actually received medical treatment ($t = 0$)	Actually received surgical treatment ($t = 1$)	Actually received medical treatment ($t = 0$)
Number of patients (n)	369	26	48	323
Number who died (s)	15 (4.1%)	6 (23.1%)	2 (4.0%)	27 (8.4%)

patients. We then have the following sequence of events:

“Eight were excluded because of diagnosis or early discharge, leaving 89 inpatients and 90 day patients. Five randomized inpatients were transferred to the day hospital because of lack of beds, and 11 randomized day patients were transferred to the inpatient unit because they were too ill for the day hospital.” [12, p. 1382]

The apparently safe method of analysis for all of these trials is based on ITT. It is the analysis that is less open to abuse and is, quite rightly, the one expected by various regulatory and other official bodies. But, as was pointed out above, it is not necessarily an estimate of the effect we are particularly interested in. What is the efficacy of the treatment? What is the effect of getting the treatment as opposed to being allocated to get it? As an estimate of treatment efficacy, the ITT estimate will be attenuated in the presence of noncompliance and/or treatment switches. But one advantage of using the attenuated ITT estimate is that it is conservative (less likely to lead to unwanted type 1 errors). Perhaps the attenuation is not such a problem – it is a way of implicitly preventing us being too enthusiastic about the trial’s results (this is presumably what the regulator wishes to see). This may be true in a trial designed to test superiority of one treatment over another, but in a trial to evaluate noninferiority or equivalence, however, the last thing we need is attenuation (bias) toward the null effect. In this case the apparent equivalence may have arisen from the noncompliance (if no one takes their tablets, it does not matter what the tablets actually contain!). The ITT estimate is not always the safe, conservative one.

Finally, loss to follow-up (failure to obtain outcome data) is also a frequent problem for the analysis

of clinical trials. And, as might be expected, loss to follow-up is often associated with noncompliance with the allocated treatment. If a patient fails to turn up for the allocated therapy, he or she is less likely to turn up for an assessment of outcome. JOBS II was a randomized prevention trial to test the efficacy of a job training intervention in prevention of deterioration in mental health as a result of job loss [13]. The control group did not have access to the training package and 46% of those offered it did not actually take up the offer. The Outcomes of Depression International Network (ODIN) trial was undertaken to evaluate the effect of psychological treatments on depression in primary care [14, 15]. A characteristic of both JOBS II and ODIN is that there was considerable loss to follow-up and that probability of having missing outcome data was dependent on the previous compliance with therapy. In ODIN, for example, about 73% of the control group provided outcome data. Of those allocated to therapy, there was 92% follow-up in the compliers, but only 55% in the noncompliers (the figures depend on the exact definition of compliance used, but they illustrate the potentially dramatic effect of compliance behavior on dropout). So, we should not ignore adherence patterns, even if we are primarily interested in estimating ITT effects. Failure to do so is likely to result in biases and invalid significance tests [16].

We now turn to the challenge of estimation in the presence of noncompliance. We first introduce the required notation and definitions of types of participant. We then introduce the complier-average causal effect (CACE) and its estimation. Following this, we review and criticize other estimation methods (per-protocol and as-treated estimates). Finally, we have another look at our causal model assumptions and warn readers against uncritically accepting the results of any of these analyses!

Notation

The notation to be used in the rest of this article is summarized in Table 1. For simplicity, we are mainly concerned with a two-arm clinical trial to compare an active treatment and a control condition, or perhaps two potentially active treatments, A and B. We use the random variable z to indicate the outcome of randomization ($z = 1$ for the active treatment, say, and $z = 0$ for the controls). We assume that receipt of treatment is all-or-none and is restricted to one of the two options made available by the randomization (life is considerably more complicated if the participant receives some of treatment A and then, for example, moves to B, or even to an unforeseen option, C). Treatment receipt is represented by the random variable T ($t = 1$ for receipt of active treatment, for example, and $t = 0$ for the control condition). R indicates availability of follow-up (outcome) data with $r = 1$ when not missing and $r = 0$ when missing. Finally, a binary outcome variable, Y , indicates treatment failure ($y = 1$) or otherwise ($y = 0$).

The results of a trial are summarized as follows: s_{zt} is the number of participants *observed* to fail (outcome $y = 1$) if randomized to arm z and receiving treatment t . The count n_{zt} is the number of participants randomized to arm z and receiving treatment t with an observed outcome, and m_{zt} is the corresponding number with a missing outcome. The total number of participants randomized to arm z and receiving treatment t is given by $n_{zt} + m_{zt}$. Finally, the total number of participants allocated to arm z is $N_z = n_{z+} + m_{z+}$.

Types of Participants

We postulate that for any given trial, prior to randomization, we have the following three types of participants [17]. Always Takers (A) are participants who will always receive treatment, irrespective of their randomized allocation. These are the people we subsequently observe to be treated when they have been allocated to the control arm of the trial. We assume that (following from randomization) on average there will be an equal number of Always Takers in the control arm, but in this case, we have no way of knowing who they might be. These are people who if, contrary to fact, they had been allocated to the controls, would have received treatment regardless. Similarly Never Takers (N) are participants who

will never receive treatment, irrespective of randomized allocation. Again we can subsequently see who they are in the treatment arm, and we assume that there will, on average, be the same number allocated to the control arm (but, again, we cannot see who they are). Finally, we postulate that there are potential compliers – participants who will receive treatment if and only if allocated to the treatment arm ($z = 1$).

It is also logically possible that there might be defiers – those who will always do the opposite of their allocation, but here, we assume that there are none.

Note that, if we are interested in measuring outcome on a simple additive (linear) scale, the ITT effect is a weighted average of the ITT effects amongst the three types of patients. Furthermore, it should be reasonable to assume that for both the Always Takers and the Never Takers, the ITT effect is, in fact, zero. Randomization makes no difference to the treatment they actually receive and we conclude therefore that it has no effect on outcome. Note that this is a pretty strong assumption, and it is always open to challenge. However, if we are prepared to accept that it is true, then the following relationship holds:

$$ITT_{All} = \pi_c \times ITT_c \quad (1)$$

Here ITT_{All} and ITT_c are the ITT effects for everyone in the trial and for the compliers, respectively, and π_c is the proportion of potential compliers in the trial. ITT_c is known as the *complier-average causal effect* [17]. It is straightforward to show that the attenuation (π_c) is estimated by the difference between the proportion of participants receiving treatment in the treatment arm and the proportion receiving treatment in the control arm (equivalent to the ITT effect on receipt of treatment). Assuming that we have a valid estimate of ITT_{All} , then the CACE estimate is simply the estimate of ITT_{All} divided by the estimate of π_c . In the hypothetical flu jab trial introduced above, ITT_{All} was estimated to be 0.02. The proportion of compliers is estimated as 0.30–0.10 (= 0.20). The effect adjusted for attenuation (CACE) is estimated as 0.10. We should bear in mind, however, that we do not know (from what we have seen so far) the proportion with a poor outcome among the compliers. We need to examine the data in slightly greater detail (but unfortunately the data to let us do this is not always reported in published trial reports).

Estimation of Complier-Average Causal Effects

No Loss to Follow-up

Table 2(a) summarizes the characteristics of the three types of trial participants, indicating their prevalence (the π 's), expected outcomes (the β 's) and ITT effects on three different measurement scales (i.e., as a risk difference, relative risk, and odds ratio (OR), *see Relative Risk; Odds and Odds Ratio*). The key assumption is that randomization has no effect on outcome in the Always Takers and in the Never Takers. Table 2(b) gives the pattern of outcome data expected according to the model parameters described and introduced in Table 2(a). In the right-hand column of Table 2(b) are given the relative frequencies (f 's) observed from the trial. We proceed by simply equating observed frequencies with their

expectations and then solving the set of simultaneous equations to get the parameter estimates. That is,

$$\pi_c \beta_{c0} = f_{00} - f_{10} \quad (2)$$

$$\pi_c \beta_{c1} = f_{11} - f_{01} \quad (3)$$

$$\pi_c = p_1 - p_0 \quad (4)$$

Therefore,

$$\widehat{\beta}_{c0} = \frac{f_{00} - f_{10}}{p_1 - p_0} \quad (5)$$

and

$$\widehat{\beta}_{c1} = \frac{f_{11} - f_{01}}{p_1 - p_0} \quad (6)$$

From these estimates of $\widehat{\beta}_{c1}$ and $\widehat{\beta}_{c0}$, we can obtain the various treatment-effect estimates given in

Table 2 A simple causal model

(a) Types of trial participant and their average treatment effects

Type	Proportion	Expected outcomes ($\Pr(Y = 1)$)		Average effects of randomization (ITT effects)		
		$Z = 0$	$Z = 1$	Risk difference	Relative risk	Odds ratio
Always Takers (A)	π_a	β_a	β_a	0	1	1
Never Takers (N)	π_n	β_n	β_n	0	1	1
Compliers (C)	$\pi_c = 1 - \pi_a - \pi_n$	β_{c0}	β_{c1}	$\beta_{c1} - \beta_{c0}$	$\frac{\beta_{c1}}{\beta_{c0}}$	$\frac{\beta_{c1}(1 - \beta_{c0})}{\beta_{c0}(1 - \beta_{c1})}$

(b) The data expected according to the model

Randomized group	Treatment received	Participant combinations			Outcome	
		Types	Pr (combination)	Observed proportion ^(a)	$\Pr(Y = 1)$	Observed fraction
0	0	N or C	$\pi_n + \pi_c$	$1 - p_0$	$\pi_n \beta_n + \pi_c \beta_{c0}$	$f_{00} = s_{00}/n_{0+}$
0	1	A	π_a	$p_0 = n_{01}/n_{0+}$	$\pi_a \beta_a$	$f_{01} = s_{01}/n_{0+}$
1	0	N	π_n	$1 - p_1 = n_{10}/n_{1+}$	$\pi_n \beta_n$	$f_{10} = s_{10}/n_{1+}$
1	1	A or C	$\pi_a + \pi_c$	p_1	$\pi_a \beta_a + \pi_c \beta_{c1}$	$f_{11} = s_{11}/n_{1+}$

^(a) p_0 and p_1 are the observed fractions of subjects receiving treatment when randomized to the control and treatment conditions, respectively

$p_0 = 48/(48 + 323) = 0.129$	$p_1 = 369/(369 + 26) = 0.934$	$\widehat{\pi}_c = p_1 - p_0 = 0.805$
$f_0 = 29/(48 + 323) = 0.078$	$f_{00} = 27/(48 + 323)$	$f_{01} = 2/(48 + 323)$
$f_1 = 21/(369 + 26) = 0.053$	$f_{10} = 6/(369 + 26)$	$f_{11} = 15/(369 + 26)$

Table 2(a). It can also be shown that these method-of-moments estimators are also maximum likelihood [18]. We can obtain standard errors (SEs) and corresponding confidence intervals (CIs) for the treatment effects *via* maximum likelihood and the delta method [18], or *via* the bootstrap [19].

Here, we work through an example (see table above), based on the surgical trial data given in Table 1.

$$\begin{aligned}\text{Risk difference (ITT)} &= f_1 - f_0 = 0.053 - 0.078 \\ &= -0.025\end{aligned}$$

$$\begin{aligned}\widehat{\beta}_{c0} &= \frac{f_{00} - f_{10}}{p_1 - p_0} \\ &= \frac{27/(323 + 48) - 6/(369 + 26)}{369/(369 + 26) - 48/(48 + 323)} \\ &= 0.0716 \\ \widehat{\beta}_{c1} &= \frac{f_{11} - f_{01}}{p_1 - p_0} \\ &= \frac{15/(369 + 26) - 2/(48 + 323)}{369/(369 + 26) - 48/(48 + 323)} \\ &= 0.0405\end{aligned}$$

$$\begin{aligned}\text{Risk difference (CACE)} &= \widehat{\beta}_{c1} - \widehat{\beta}_{c0} \\ &= 0.0405 \\ &\quad - 0.0716 \\ &= -0.031 \\ &= (f_1 - f_0)/\widehat{\pi}_c \\ &= -\frac{0.025}{0.805} \\ &= -0.031\end{aligned}$$

$$\text{Relative risk (CACE)} = \frac{0.0405}{0.0716} = 0.566$$

$$\begin{aligned}\text{Odds ratio (CACE)} &= 0.0405 \times \frac{(1-0.0716)}{(1-0.0405)} \times \\ 0.0716 &= 0.547 \text{ (i.e., } \log(\text{OR}) = -0.603\text{)}.\end{aligned}$$

Coping with Nonignorable Missing Data

Now, let us assume that we have missing outcome data and that the missing data mechanism is what has been called *latently ignorable (LI)* [16]. The essence of this missing data model is that the probability of providing outcome data depends on the type of participant (which is latent or hidden), and also that randomization may have an effect on the proportion with follow-up data in the compliers, but has no effect in either the Always Takers or the Never Takers. Note, again, that these strong assumptions are always open to challenge. The revised model (now a joint model for both outcome and nonmissing data) is shown in Tables 3 and 4. Again, we can equate observed frequencies with their expectations, and solve the resulting simultaneous equations, as follows:

$$\pi_c \phi_{c0} \beta_{c0} = f_{00}^* - f_{10}^* \quad (7)$$

$$\pi_c \phi_{c1} \beta_{c1} = f_{11}^* - f_{01}^* \quad (8)$$

$$\pi_c \phi_{c0} = q_{00} - q_{10} \quad (9)$$

$$\pi_c \phi_{c1} = q_{11} - q_{01} \quad (10)$$

Therefore,

$$\widehat{\beta}_{c0} = \frac{f_{00}^* - f_{10}^*}{q_{00} - q_{10}} \quad (11)$$

and

$$\widehat{\beta}_{c1} = \frac{f_{11}^* - f_{01}^*}{q_{11} - q_{01}} \quad (12)$$

Again, we can provide SEs or CIs *via* maximum likelihood and the delta method [18], or *via* the bootstrap. We illustrate the calculations by reference

Table 3 Allowing for missing follow-up – types of trial participant and their average treatment effects

Type	Proportion	Probability of follow-up (Pr($R = 1$))		Expected outcomes (Pr($Y = 1$))	
		$Z = 0$	$Z = 1$	$Z = 0$	$Z = 1$
Always Takers (A)	π_a	ϕ_a	ϕ_a	β_a	β_a
Never Takers (N)	π_n	ϕ_n	ϕ_n	β_n	β_n
Compliers (C)	$\pi_c = 1 - \pi_a - \pi_n$	ϕ_{c0}	ϕ_{c1}	β_{c0}	β_{c1}

Table 4 Patterns of outcomes and missing data (assuming latent ignorability)

(a) The nonmissing data expected according to the missing data model

Z	T	Types	Pr (types)	Observed proportion	Nonmissing outcome	
					Pr($R = 1$)	Observed fraction
0	0	N or C	$\pi_n + \pi_c$	$1 - p_0$	$\pi_n \phi_n + \pi_c \phi_{c0}$	$q_{00} = n_{00}/(n_{0+} + m_{0+})$
0	1	A	π_a	$p_0 = (n_{01} + m_{01})/(n_{0+} + m_{0+})$	$\pi_a \phi_a$	$q_{01} = n_{01}/(n_{0+} + m_{0+})$
1	0	N	π_n	$1 - p_1$	$\pi_n \phi_n$	$q_{10} = n_{10}/(n_{1+} + m_{1+})$
1	1	A or C	$\pi_a + \pi_c$	$p_1 = (n_{11} + m_{11})/(n_{1+} + m_{1+})$	$\pi_a \phi_a + \pi_c \phi_{c1}$	$q_{11} = n_{11}/(n_{1+} + m_{1+})$

(b) The outcome data expected according to the combined missing data and outcome models

Z	T	Types	Pr (types)	Outcome	
				Pr($Y = 1$)	Observed fraction
0	0	N or C	$\pi_n + \pi_c$	$\pi_n \phi_n \beta_n + \pi_c \phi_{c0} \beta_{c0}$	$f_{00}^* = s_{00}/(n_{0+} + m_{0+})$
0	1	A	π_a	$\pi_a \phi_a \beta_a$	$f_{01}^* = s_{01}/(n_{0+} + m_{0+})$
1	0	N	π_n	$\pi_n \phi_n \beta_n$	$f_{10}^* = s_{10}/(n_{1+} + m_{1+})$
1	1	A or C	$\pi_a + \pi_c$	$\pi_a \phi_a \beta_a + \pi_c \phi_{c1} \beta_{c1}$	$f_{11}^* = s_{11}/(n_{1+} + m_{1+})$

to a hypothetical community care (or day care) trial for patients suffering from schizophrenia [20]. Table 5(a) shows the underlying structure of the data (but not that which is observed). The table

presents the observed number of treatment failures in each category, the total number with an observed (nonmissing) outcome and, finally, the total number randomized at the beginning of the trial. Table 5(b)

Table 5 Results of a hypothetical trial of community care (counts)

(a) The true data structure (counts)

		Complier	Never inpatient	Always inpatient
Randomized to day care ($z = 1$)	Failures	200	10	180
	Observed	400	50	200
	Total	500	200	300
Randomized to inpatient care ($z = 0$)	Failures	100	10	180
	Observed	300	50	200
	Total	500	200	300
True CACE		$= 200/400 - 100/300$ $= 6/12 - 4/12$ $= 1/6$		

(b) What we observe (counts)

	Randomized to day care ($z = 1$)		Randomized to inpatient care ($z = 0$)	
	Received day patient care ($t = 1$)	Received inpatient care ($t = 0$)	Received day patient care ($t = 1$)	Received inpatient care ($t = 0$)
Total	700	300	200	800
Nonmissing (n)	450	200	50	500
Missing (m)	250	100	150	300
Poor outcome (s)	210	180	10	280

shows the data that would actually be observed in such a trial. From these data, we can calculate the following:

$$\begin{aligned} f_{00} &= 280/1000 & q_{00} &= 500/1000 & p_1 &= 700/1000 \\ f_{01} &= 10/1000 & q_{01} &= 50/1000 & p_0 &= 200/1000 \\ f_{10} &= 180/1000 & q_{10} &= 200/1000 & p_1 - p_0 &= 0.5 \\ f_{11} &= 210/1000 & q_{11} &= 450/1000 \end{aligned}$$

It follows that, from equations (11) and (12), respectively

$$\begin{aligned} \widehat{\beta}_{C0} &= \frac{(280 - 180)}{(500 - 200)} = 1/3 \\ \widehat{\beta}_{C1} &= \frac{(210 - 10)}{(450 - 50)} = 1/2 \end{aligned}$$

The estimated risk difference (CACE) is $\widehat{\beta}_{C1} - \widehat{\beta}_{C0} = 1/2 - 1/3 = 1/6$. The corresponding OR (CACE) = 0.50 (i.e., logOR = -0.693).

Use of Negative Weights

Our statistical models specify that the number of negative outcomes for the Always Takers is the same, on average, in both arms of the trial. This is true under latent ignorability (but not necessarily other missing data mechanisms) and therefore also when there are no missing outcome data. The models also specify that the number of positive outcomes for the Always Takers is the same, on average, in both arms of the trial. And the same two equalities also apply to the Never Takers. Now, it may be the case that we have not used an exact 1:1 randomization. In this case, we simply make the necessary allowance for the lack of equality in the sizes of the two arms.

The method used here simply involves a straightforward regression (or *logistic regression* (see **Logistic Regression**), and so on, depending on the outcome) of outcome on treatment received where known noncompliers (the Never Takers in the treatment arm and the Always Takers in the control arm) are given a weight of -1. Everyone else is assigned a weight of +1. In the case of unequal randomization the weight of -1 for the known Never Takers is replaced by $-N_0/N_1$ and, similarly, the weight of -1 for the Always Takers is replaced by $-N_1/-N_0$, where N_1 and N_0 are the total number of participants

randomized to the treatment and control arms, respectively. Essentially the weights for the known Always Takers in the control are being used to “cancel out” or combine with the equivalent number of hidden Always Takers in the treatment arm. Similarly, the known Never Takers in the treatment arm cancel out the hidden ones in the control arm. What is left leads to an estimate of the effect of treatment in the compliers (i.e., the CACE). For further details, see [9] or [21]. SEs and CIs for the CACE estimates are obtained through the use of the bootstrap. Returning to the surgery trial summarized in Table 1, the use of this simple procedure using negative weights yields a risk difference of -0.031 (as before). The use of a thousand bootstrap replications yields an estimated SE of 0.023 and a 95% CI (percentile method) for the CACE of (-0.076, +0.015). A similar logistic regression yielded an estimated logOR of -0.602 (SE 0.058) with a 95% CI of (-1.713, +0.252). The point estimate is identical to that found earlier.

If we apply the same method to the hypothetical community care trial, we obtain a risk difference of +0.167 (SE 0.058) and a logOR of 0.693 (SE 0.281) with 95% CIs of (+0.057, +0.283) and (+0.265, +1.366), respectively. Again, the point estimates are those that we obtained earlier.

Potentially Invalid Estimators – as Treated and per Protocol

Most attempts made to allow for noncompliance use an “as-treated” or a “per-protocol” analysis. In the first, we simply look at the differences in outcomes for those who receive treatment and those who do not, irrespective of randomization. Per protocol looks at the same differences; however, data from those participants known to be noncompliers is first discarded. These methods only provide a valid effect of the treatment (efficacy) if compliers and noncompliers do not differ systematically in their disease state or prognosis. In practice, this is unlikely to be the case, so selection bias occurs. Heart disease patients who comply with their prescribed medication, for example, are also those who are likely to improve their diet or take more exercise and these changes, in turn, are likely to lead to a better outcome. Selection bias may often be reduced by adjustment for baseline covariates, but there is still no guarantee of an unbiased analysis. Returning to the heart surgery data in

Table 1, the estimated as-treated risk difference is $17/417 - 33/349 = -0.054$. The estimated per protocol risk difference is $15/369 - 27/323 = -0.043$. Both methods appear to be overestimating the impact of treatment.

Treatment Effect Heterogeneity

Potential treatment-effect heterogeneity is a well-known problem in generalizing the findings (ITT effects, for example) from participants in a given trial to the population as a whole. Treatment noncompliance, however, introduces more subtle problems for inferences concerning generalizability. We have demonstrated above how one might use data from a randomized clinical trial to estimate the effect of an intervention or treatment when there is a substantial amount of noncompliance with the allocated intervention. We have achieved this by concentrating on the average effect of randomization (ITT effect) on those who only receive the treatment if and only if they are allocated to receive it (i.e., the potential compliers). We have shown how to estimate this CACE using maximum likelihood both when there are no missing outcome data and when the missing data are latently ignorable. It is important that the reader realizes that we have done exactly what “CACE” implies we have done – we have estimated the effect of receipt of treatment in the compliers. We have no idea what the effect of treatment was in the Always Takers – we have no data on these people in the untreated condition. We cannot estimate the average effect of treatment in the Always Takers unless we are willing to assume that is the same as that in the compliers and what about the Never Takers? Again, we have no informative data. What if we carry out a second randomized controlled trial (RCT), and this time change our procedures so that we get much better compliance with the allocated interventions? What if we achieve complete compliance? Assuming that the treatment has not changed in any way, should we expect the treatment effect in the compliers in this second trial to be the same as in the first? Possibly not. Perhaps the treatment effect is associated with the participant’s propensity to adhere to the offered treatment. If we unrealistically assume that we have treatment-effect homogeneity (the treatment has the same effect in everyone), then we can use CACE estimates to infer the average effect of treatment for everyone in the

trial if, contrary to fact, we had persuaded everyone to adhere with their treatment. If we relax this unrealistic assumption and admit that the treatment effects vary from one participant to another, and, in particular, are likely to be associated with a participant’s willingness to adhere to the offered treatment, then we have to be very wary about making such inferences.

Computer Security: A Historical Perspective

Computer systems have evolved from single isolated machines to billions of machines of myriad sizes, with massive interconnection over pervasive global networks. Security alternatives for computers and their networks have grown from external physical protective measures toward relying on the computers themselves to protect information essential to the vital interests, if not the survival, of enterprises. Today the threat of professional attack is serious and growing, and computers are increasingly a major source of risk.

The problem of security was not really noticed during the first two decades of use of electronic digital computers: the entire system was dedicated to a single user. Where early computers were used to process sensitive information, requirements for its security were addressed outside the computer with physical security for the facility. The computer itself was not really part of the security problem, nor was it part of its solution.

The demand for more efficient use of computers in the 1960s gave birth to multiplexing technologies, resource sharing operating systems, virtual machines, multiprogramming, and various other techniques that are still widely used. These computers were generally still used in so-called benign environments. In the 1970s and 1980s, the need to share not only resources but also information intensified. Often, this sharing was among users with disparate authorization for information access. This made controls internal to the computer system essential to mediate access of people to information in order to prevent unwanted modification and disclosure. These internal controls are the core of what we call *computer security* (see **Epidemiology as Legal Evidence; Game Theoretic Methods**).

As the 1980s approached, a published Consensus Report [1] stated, “It is a fact, demonstrable by any of several studies, that no existing commercially-produced computer system can be counted upon to protect any of its moderately knowledgeable users from having complete and undetectable access to any information in the system, no matter what kinds of so-called security features or mechanisms have been built into the system.” That truth has persisted into the twenty-first century, yet the emergence of the

Internet and the “information age” have dramatically increased our societal and economic dependence on computers.

Furthermore, computers are an increasingly critical part of marketed security solutions, with offerings like firewalls, virtual private networks, intrusion detection, file encryption devices, etc. However, the risks from using computers continue to grow, largely unabated, in spite of the billions of dollars (across the industry) spent on such solutions. So it is increasingly important to be able to assess the risks relating to computer security. The current (early twenty-first century) state of computer (in)security and associated risks is the focus of the rest of this article.

Theory of Computer Security

Computer security plays an important role in overall *system security* (see **Use of Decision Support Techniques for Information System Risk Management**). System security includes the broad range of *external* (to the computer) controls having to do with environment, people, procedures, and physical security practices that contribute to the security of the system. *Computer security* concerns the *internal controls* that the computer hardware and software – the trusted computing base (TCB) – provides to secure the enterprise information entrusted to its care. *Assurance* deals with the confidence, and the reasons for that confidence, one can have that the internal controls provided by a computer will provide the computer security expected – especially when faced with a deliberate, malicious professional attack.

Security of information inside a computer is very difficult to ensure. This is true because the “game of wits” between attacker and defender is unbalanced: an attacker bent on modification or disclosure has a substantial advantage. The system designer must anticipate every possible way to circumvent security and correct (prevent) them all; the attacker is interested in finding and using one. This is why computer security is fundamentally “hard”.

Numerous efforts to design reliable internal security controls by various *ad hoc* means have proved unsuccessful. Furthermore, technology investigations, including those by Anderson [2] and Schell [3], have consistently concluded that it is impractical to ensure that traditional internal controls contain no security

flaws. In fact, Harrison *et al.* [4] showed that it is theoretically impossible (i.e., mathematically “undecidable”), in general, to determine whether an arbitrary protection system can prevent a (possibly malicious) process from gaining unwanted access to information. This helps underscore the futility of relying (only) on testing to identify security holes: testing can only prove the presence of flaws and not their absence. Similarly, Karger and Schell [5] showed that depending on an audit log of accesses to secure a computer system is futile, because the attacker is likely to eliminate or mask any record of the attack on the security controls. Such log scrubbing is now routine, and indeed, there are automated kits to do so for major operating systems, which make them easy for even amateur attackers to use.

Not only do we want to create a computer that is secure, but we also need to know whether we have succeeded. In 1969 and 1970, a distinguished panel, headed by Dr Willis Ware of Rand Corporation, developed and published a seminal report [6] concluding that it is very difficult to evaluate a system and determine whether it provides adequate security. The previous paragraph summarized the major findings of the somewhat later Air Force panel headed by E. L. Glaser run under a contract with James P. Anderson (both members of the panel headed by Ware). This later panel published a report [2] that identified research aimed at solutions to problems identified by the Ware panel. The objective of this research was to understand the nature of the computer security problem and provide a framework for solutions. This, in turn, should make it practical to systematically evaluate the security of a system and use this evaluation as a basis for a risk assessment when using a system created within this framework. We will next examine the results of this research and development.

Nature of the Problem

A given system is secure only with respect to some specific security policy. A security policy is the set of rules that prescribe what information each person can access. The security policy is conceptualized in a way that is independent of (i.e., external to) computers.

Internal security controls are those rules enforced by computer hardware and software to govern access to system data and processing resources. In the 1970s,

the computer security profession identified a taxonomy of computer security functionality with four principal elements. These elements are elaborated on in the section titled “Framework for Solutions”. To support systematic risk assessment, these security function categories were embodied in the Trusted Computer System Evaluation Criteria (TCSEC) [7] and are still in widespread use today:

1. *Mandatory access controls* (rules that apply to all users in all circumstances).
2. *Discretionary access controls* (rules that can be changed by users and administrators authorized to do so, while the system is running).
3. *Identification and authentication* (I&A) (rules that control who may interact with the system and how their identity is verified).
4. *Audit* (rules that require certain events, trends, or changes in system state or configuration be recorded for later analysis and reporting).

Development of early military systems concluded that some portions of the system require particularly strong security enforcement. Specifically, this enforcement was necessary to protect data whose loss would cause extremely grave damage to the nation. Systems that handled such data, and that simultaneously included interfaces and users not authorized to access such data, came to be known as *multi-level*. This term was never intended to be limited in meaning to “hierarchical”, as it also applied to non-hierarchical, well-defined (but unrelated) user groups. This security policy is what is called *mandatory access control* (MAC) policy in the policy taxonomy, above. There are elements analogous to MAC policy in the commercial context that distinguish information essential to the crucial interests, or even the survival, of enterprises.

Much of the nature of the problem of computer security can be illustrated by examining common methods used to enforce the four policy elements, and, in particular, the MAC. These methods are reflected in a common categorization of computer control modes, using terms from the military context:

1. Dedicated mode

All users allowed access to the system are cleared for the highest level of information contained in the system and have a need-to-know for all the information in the system (i.e., it is dedicated to processing for users with a uniform need-to-know

for information at a given single security level). All users, equipment, and information reside within a protective boundary or security perimeter. Protection or security is enforced by physical means external to the computer (fences, guards, locked doors, etc.).

2. System high mode

The computer not only provides computation, but also must internally provide mechanisms that separate information from some users. This is because not all users of the system have a need-to-know for all the information contained in the system (but all are cleared for the highest level of information in the system). Discretionary access control (DAC), I&A, and audit controls are available in order to avoid (or recover from) user error.

3. Multilevel mode

The computer must internally provide mechanisms that distinguish levels of information and user authorization (i.e., clearance). This implies enforcement of a MAC policy. In this case, not all users of the system are cleared for the highest level of information contained in the system. This mode intrinsically requires that the computer operating system and hardware are what the military would term multilevel secure (MLS).

Each of these three modes of operation faces a very different computer security problem, i.e., requirement for internal controls.

1. The *dedicated mode* has no computer security responsibilities. Everything within the security perimeter in which the computer is located is considered benign. The computer system is not expected to seriously “defend” information from any of its users because they are considered non-malicious by virtue of their security clearances and need-to-know.
2. The computer security requirements for the *system high mode* are not very demanding, because the risk from vulnerabilities in these non-MAC controls is constrained. As in the dedicated mode, all users are considered benign, and while not every user may have need-to-know access to all data, all users are, nevertheless, cleared to see all data. DAC is therefore considered adequate to assist users in adhering to need-to-know policies.
3. The most serious risk (e.g., extremely grave damage to the nation) and the most difficult problem

are in providing adequate assurance of the MAC controls for the *multilevel mode*. Here, the computer system must protect the information from the user who is not cleared for it and who may attempt to install and execute *malicious software*. In effect, the computer system must become part of the security perimeter. The internal protection mechanisms must “assume the role” of the guards, fences, etc., that are indicative of the external security perimeter. Anything outside the security perimeter (including software) should be considered suspicious, since it may be malicious.

The remainder of this article will have a significant focus on computer security for this MAC policy.

Framework for Solutions

As noted above, the threats to computer security can be countered by providing access control over information on a computer to ensure that only specifically authorized users are allowed access. What we desire is a set of methods that make it possible to build a relatively small part of the system in such a way that one can even allow a clever attacker who employs malicious software to build the rest of the system and its applications, and it would still be secure. The theory of computer security gives us this.

Understanding computer security involves understanding and distinguishing three fundamental notions:

1. a security *policy*, stating the laws, rules, and practices that regulate how an organization manages, protects, and distributes sensitive information;
2. the *functionality* of internal mechanisms to enforce that security policy; and
3. *assurance* that the mechanisms do enforce the security policy.

The following introduces these three important notions and describes how they pertain to the reference monitor concept, which provides us with a set of principles that can be applied both to the design or selection of security features and to their implementation in ways that provide a high degree of resistance to malicious software. We then proceed to introduce the reference monitor concept as we apply it in designing secure computer systems.

Precise Policy Specification – What Does “Secure” Mean? We have already noted that a basic principle of computer security is that a given system can only be said to be “secure” with respect to some specific security policy, stated in terms of controlling access of persons to information. It is critical to understand the distinction between security policy and security mechanisms that enforce the security policy within a given computer system. For example, mechanisms might include type enforcement, segmentation, or protection rings [8]. These are all mechanisms that may be used within a computer system to help enforce a security policy that controls access of persons to information, but none of these is itself a security policy. Such mechanisms provide functionality that enables the implementation of access control within the computer system, but they do not directly represent rules in the security policy world of persons and information.

As noted earlier, a useful taxonomy for policy uses four principal elements of computer security functionality, and these in turn can be considered in two classes: access control policy is that portion of the security policy that specifies the rules for access control that are necessary for the security policy to be enforced. Supporting policy is the part that specifies the rules for associating humans with the actions that subjects take as surrogates for them in computers to access controlled information, most notably audit, and identification and authentication. We do not deal with supporting policy in greater detail.

The access control policies in turn fall into two classes: discretionary and mandatory. These two classes were described early on by Saltzer and Schroeder [9]. Both have historically been considered necessary for commercial as well as military security. We may characterize one control pattern as discretionary, implying that a user may, at his own discretion, determine who is authorized to access the objects he creates. In a variety of situations, discretionary access may not be acceptable and must be limited or prohibited. This is often described as enforcing “need-to-know” and in other cases reflects “role-based” controls.

A MAC policy contains mandatory security rules that are imposed on all users. It provides an overriding constraint on the access to information, with the highest assurance of protection possible, even in the face of Trojan horses and other forms of malicious software. This class of security policy can always be

represented as a (partially ordered) set of sensitivity labels for information (“classification”) and users (“clearance”).

As a practical matter, the choice between mandatory and DAC policies to support a particular security policy is, in most cases, tied to the penalty for which one would be liable if one violated the policy in the “paper world” – if no computers were being used. If the person responsible for protecting the information could get into “real trouble” (e.g., lose a job, get sued, be placed in jail, or even be severely reprimanded) for violating the policy in the paper world, then a MAC policy should be employed to protect the information in the computer.

Reference Monitor^a – Principles for a Security Perimeter also known as (aka TCB). The reference monitor provides the underlying “security theory” for conceptualizing the idea of protection, thereby permitting one to focus attention only on those aspects of the system that are relevant to security. The reference monitor provides a framework for extending the concept of information protection commonly used for people accessing sensitive documents to processors accessing memory. The abstract models of Lampson [10] were adapted to form the reference monitor concept, which is illustrated in Figure 1.

The reference monitor [2] is an abstraction that allows active entities called *subjects* to make reference to passive entities called *objects*, based on a set of current access authorizations. The reference monitor is interposed between the subjects and objects. The correspondence between reference monitor components and components of the computer system is reasonably clear: the *subjects* are the active entities in the computer system that operate on information on behalf of the system’s users. The subjects are processes executing in a particular domain (see below for

Figure 1 Reference monitor

definition) in a computer system (i.e., a $\langle$ process, domain $\rangle$ pair). Most of the subjects carry out the wishes of an individual, i.e., are a surrogate for a user.

The *objects* hold the information that the subjects may access. A domain of a process is defined to be the set of objects that the process currently has the right to access according to each access mode. Two primitive access modes, read and write, are the basis for describing the access control policy. While there are many kinds of objects in general, we can think of objects as well-defined portions of memory within the computer, most commonly memory segments. Files, records, and other types of information repositories can be built from these primitive objects, over which the reference monitor has total control. The reference monitor controls access to them by controlling the primitive operations on them – the ability to read and write them.

As a refinement on this concept, the section titled “Accreditation – Leveraging Technical Evaluation” discusses the simplifying technique of “balanced assurance” that allows constructing the named objects upon which DAC is enforced out of segments outside the reference monitor implementation. In fact, some reference monitors and their associated models address only the MAC policy.

The reference monitor itself is that most primitive portion of the computer system that we rely on to control access. We can think of implementing the reference monitor with a subset of a computer’s operating system and hardware. We shall find that, to be practical and efficient, the operating system software needs the assistance of computer hardware that is well suited to the task of providing security. A security kernel is defined [2] as the *hardware* and *software* that implement the reference monitor. (In a specific context, where the hardware context is static, “security kernel” is sometimes used in reference to just the software.)

Security Kernel as an Implementation of Reference Monitor. Employing a security kernel is the only proven way to build a highly secure computer system. Security kernel technology provides a theoretical foundation and a set of engineering principles that can be applied to the design of computer systems to effectively protect against internal attacks, including those that the designers of the system have never considered. A security kernel provides an effective security perimeter [11] inside which the information

is protected, no matter what happens outside. In fact, an implicit assumption in the design of a security kernel is that the attackers may build the remainder of the system, and yet the kernel will remain effective in prohibiting unauthorized access.

A security kernel [12] is a small, basic subset of the system software and supporting hardware that is applicable to all types of systems, wherever the highly reliable protection of information in shared-resource computer systems is required – from general-purpose multiuser operating systems to special-purpose systems such as communication processors. The implication of the term *security kernel* is that we can design a hardware/software mechanism that meets exactly the requirements for a reference monitor. This *reference monitor implementation* in a computer system must meet a set of requirements that were first identified in [2] and have been historically referred to as completeness, isolation, and verifiability:

- *Completeness* – all subjects must invoke the reference monitor on every reference to an object.
- *Isolation* – the reference monitor and its database must be protected from unauthorized alteration.
- *Verifiability* – the reference monitor must be small, well-structured, simple, and understandable so that it can be completely analyzed, tested, and verified to perform its functions properly.

The linchpin in providing the desired verifiable protection is a formal security policy model describing the core security policy to be enforced in this implementation of the reference monitor. Its properties are mathematically proved to be sound and correct. The system interface operations of the security kernel correspond to one or more rules that represent the security policy. All elements of the system must be demonstrated to be both necessary and sufficient for enforcement of the policy. The implementation is systematically traced to the policy. This includes showing that the entire code that is in the kernel is required for policy enforcement and system self-protection – this process is commonly termed *code correspondence*. The model enforced by most security kernels is derived from what is commonly referred to as the *Bell and LaPadula Model* [13]. This model provides rules that are provably sufficient for preventing unauthorized observation and modification of information.

The security kernel functions form its interface with the rest of the operating system and are derived from the formal security policy model. It turns out that, to meet the constraints of the security policy model for the MAC policy, the security kernel interface will provide a pure virtual environment for the rest of the system. This requirement results from the need to eliminate (sometimes subtle) methods of circumventing the security policy model's restrictions on the flow of information from one level to another. Frequently, specifications of the interface are expressed in a formal language capable of being analyzed by a computer program and of supporting a formal proof that the specifications conform to the requirements of the security policy model. Such a specification is termed a *formal top-level specification (FTLS)*.

Several different hardware platforms have been the target for security kernels. They each had common properties, however, including memory *segmentation* [9] and at least three hardware states for use in implementing *protection rings* [8]: one for the security kernel; one for the operating system; and one for applications. A system whose interface has been specified and proven in this manner is a system for which one has significantly increased assurance in its ability to verifiably enforce the security policy. A recent article by Anderson *et al.* [14], summarized its description of the problems addressed by the security kernel technology as follows:

As adversaries develop Information Warfare capabilities, the threat of information system subversion presents a significant risk. System subversion will be defined and characterized as a warfare tool. Through recent security incidents, it is shown that means, motive, and opportunity exist for subversion, that this threat is real, and that it represents a significant vulnerability. Mitigation of the subversion threat touches the most fundamental aspect of the security problem: proving the absence of a malicious artifact. A constructive system engineering technique to mitigate the subversion threat is identified.

A system so designed contains a security kernel and eliminates opportunities for professional attackers to use subversion to plant artifices, as any function that does not relate back to the policy model will be discovered in the "code correspondence" mapping process. This confirms there is no extraneous code and the system is shown to do what it supposed to do – and nothing more.

Taxonomy of Criteria – Risk and Security

As a practical matter, risk assessment requires that policy differentiate, or "classify", information on the basis of how much it is worth. There are two perspectives: (a) what the information is worth to an attacker and (b) what it would cost an enterprise if the secrecy or integrity of the information is lost. The value of information from the perspective of an attacker is critical to risk assessment because it is a factor in the motivation of and resources an attacker will employ, if given the opportunity. The cost of information loss from the perspective of the enterprise is critical because it yields an analytical justification for a level of expenditure to counter the risk. This is touched on further under section titled "Classification of Threats and Accepted Risk".

In the commercial world, the value of information, if measured at all, is likely to be measured in monetary terms. Metrics, in illustrative contexts, might include the average cost incurred per credit card record lost to hackers, the prospective decline in stock price (market capitalization) following a security incident, or the capitalized value of a proprietary technology advantage. In the public sector, an illustrative qualitative metric is given by regulations requiring the US government to classify information as "top secret" if its "loss would cause extremely grave damage to the nation".

In addition to the financial analyses hinted at above, the classification of data also yields the prerequisite analytical foundations for computer security. As discussed above, powerful computer security technology leverages a well-defined MAC security policy, and a MAC policy must express information classification.

Need for data classification

From a historical perspective, the use of computers to process sensitive information has clarified the value of a more systematic classification framework. In the early 1980s a "Data Security Leaders Conference" [15] recommended that managers "... assess the sensitivity of the data. Few companies examine the nature of data and rank it by sensitivity. Management must address this subject if they are going to take security seriously." The same report continues, calling this "... data classification. This is a new issue, one that has drawn little attention. But it is important, if management is going to know how much

money to spend to achieve an appropriate level of data security.” Unfortunately, although this was considered “a new issue” 25 years ago, its significance is often still unfamiliar to those assessing risk.

Need for security evaluation

Although data classification is necessary, it is not sufficient for an assessment. The same 1980s conference expressed concern for “evaluation procedures for assessing computer security. Without them, data security is a meaningless, costly exercise.” It went on to argue, “that users had too many choices for securing a system but no way of determining which would help really fend off potential data abusers.” Since that time, information security has become a multibillion dollar industry with many more choices. This cries out for criteria for assessing the “solutions” that the industry offers.

Objectives of Assessments

A taxonomy for criteria looks at the factors affecting quantitative analysis of risk in the realm of computer security. At the most general, risk assessments will be either Boolean in their ability to declare a system secure or not, or to offer some probabilistic estimate of the likelihood that the system is not secure. The ability (or inability) to state that a system is free of major security-impacting defects is precisely the factor that determines whether the system can be considered “secure”. For modern systems, a taxonomy must consider determined, intentional attacks that will often use malicious software. These attacks succeed (i.e., the system is not secure) because of the widespread lack of attention to what behaviors a system exhibits beyond those required or expected of it.

Penetration testing was among the first attempts at evaluating the security of a computer system, but the futility of substantially relying on that method for a security evaluation became known relatively early. In the early days of computer security, advocates of secure systems tried to follow a path of searching for ways to penetrate the systems’ controls. Their plan was that, failing to penetrate a system, they could then plausibly argue that there was no way to penetrate the system, since no way was known (to them). In this scenario, if a security hole is found, it can first be patched before the argument for security is made.

However, this argument suffers from both theoretical and practical difficulties. The approach presumes that one could test all possible programs to find any that led to a security penetration. If possible, this method of exhaustion would be effective, but it is far beyond the realm of feasibility. For any real computer, it would take so long that before the evaluation was finished, the sun would literally have burned out! Thus any evaluation conducted by exhaustion must be so incomplete as to be ludicrous.

The lesson that was learned is that a test can demonstrate the presence of an error but, short of exhaustion of every possible combination of inputs, it cannot demonstrate the absence of errors. Practically speaking, the effort spent in penetrate-and-patch techniques yields poor marginal return in terms of security [3].

Functional testing, penetration testing, and related quality assurance efforts can never explore all possible combinations and permutations of system state that may be used as “keys” to unlock trapdoors hidden in code. Protecting vital information from deliberate attack requires verification of what the system will *not* do, at least as much as knowing what the system *will* do. Only with a systematic mapping of the selected security policy to a formal security model, and of the model to a system (hardware and software) design (e.g., a security kernel), is it possible to determine what the system will do and *not* do. The objectives of risk assessment are related to three common aspects that are addressed next.

Certification – Reusable Technical Evaluation Results. One major component of risk assessment is systematic technical evaluation of the TCB that, as noted earlier, is at the core of computer security. The TCB is the totality of protection mechanisms within a computer system – including hardware, firmware, and software – the combination of which is responsible for enforcing a security policy. It creates a basic protection environment and provides additional user services required for a trusted computer system. The ability of a TCB to correctly enforce a security policy depends solely on the mechanisms within the TCB and on the correct input by system administrative personnel of parameters (e.g., a user’s clearance) related to the security policy [7].

A technically sound foundation for evaluation enables it to be used by a third party to accurately and objectively measure security trustworthiness of

a system. It does this in a manner which does not require the highly skilled and experienced scientists who wrote the criteria to apply it, yet which allows those less experienced who apply the criteria to come to the same conclusion as would those who wrote it. Those who apply the criteria should not be simultaneously writing and interpreting the criteria; that situation only leads to inequities in applying the criteria as interpretations differ between evaluations.

Historically, as pointed out by Bell [16], part of the original motivation for the TCSEC [7] and the Trusted Product Evaluation Program (TPEP) was to streamline and regularize the formal process of approving Department of Defense (DoD) systems for operation – certification and accreditation (C&A). While there were policies and procedures for assessing secure computer systems, there were problems with having engineering staff of each acquisition assess the underlying operating system or systems for security compliance. Not only was there no reuse of the analytical results, but also there was no guarantee of consistency across acquisitions. If all certification engineers facing a component could refer to a published summary of its security properties in the context of its TCSEC rating, then redundant analyses would be avoided and consistency across different acquisitions would be increased. Moreover, since computer security was a specialty field, the acquisition engineering staff was not always trained and current in the relevant security topics. The intention was to centralize and reuse the security evaluation results to obviate redundant analyses, to assure consistent results, and thus to provide an acquisition task with a solid, published product evaluation report.

Certification has been defined [17] as a comprehensive assessment of the management, operational, and technical security controls in an information system, made in support of security accreditation (see the next section), to determine the extent to which the controls are implemented correctly, operating as intended, and producing the desired outcome with respect to meeting the security requirements for the system. A reusable technical evaluation of the TCB can be major contribution to certification.

Accreditation – Leveraging Technical Evaluation.

Accreditation has been defined [17] as the official management decision given by a senior agency official to authorize operation of an information system and to explicitly accept the risk to agency

operations (including mission, functions, image, or reputation), agency assets, or individuals, based on the implementation of an agreed-upon set of security controls. This can be [18] made on the basis of a certification by designated technical personnel of the extent to which design and implementation of the system meet prespecified technical requirements, e.g., TCSEC, for achieving adequate data security. The management can accredit a system to operate at a higher/lower level than the risk level recommended for the certification level of the system. If the management accredits the system to operate at a higher level than is appropriate for the certification level, the management is accepting the additional risk incurred.

Historically, David Bell has noted [19] that in the DoD, the Trusted Product Evaluation Program was a program to evaluate and record the fidelity of commercial products to classes within the TCSEC, for later use by system certifiers and accreditors. Products successfully completing a “formal evaluation” were placed on the *evaluated products list (EPL)*.

Composition – Certification and Accreditation Implications.

In dealing with any complex system, an attractive strategy is one of “divide and conquer”. What is desired is an approach for dividing the trusted component of the system into simpler parts, evaluating each of the parts separately, and then validating the correctness of the way the parts are composed to form a single system enforcing a globally well-defined security policy. It is obviously desirable that the validation of the correct composition of evaluated parts be a relatively simple task.

In the general case, this is very difficult. David Bell has pointed out [16] that the growth of networking brought the “composition problem” to the fore: what are the security properties of a collection of interconnected components, each with known security properties? Efforts were made to derive methods and principles to deal with the unconstrained composition problem, with limited success. In the sense of product evaluation and eventual system certification, and accreditation, one needed to leverage the conclusions about components to reach conclusions about the whole, without having to reanalyze from first principles. Unfortunately, closed-form, engineering-free solutions were not discovered and may not be possible.

Fortunately, the simplicity of the reference monitor concept lends itself well to a “divide and conquer” evaluation strategy. In this section, two distinct strategies are overviewed. These are two strategies that are very useful in practice, but reflect constraints on composition that allow them to avoid the hard problems of unconstrained composition mentioned above. These ideas are an extension of the principles first described in [20], with the benefit of several additional years of experience and thought about how a complex TCB might be composed from a collection of simpler TCBs residing in individual protection domains.

Incremental evaluation of distinct physical components. The first strategy, the “partition evaluation” of a trusted distributed system or network, depends upon the notion that a complex system may be decomposed into independent, loosely coupled, intercommunicating processing components. This strategy is most suitable for trusted systems that have a complex physical architecture (e.g., distributed systems or networks). In such cases, it is not practical to require that an entire system be evaluated at once, so a strategy is needed for supporting incremental evaluations. The question is: how does one build a system from a set of individual components that were previously evaluated? The answer is found in two key concepts: (a) the concept of a “*partitioned TCB*”, in which individually evaluated components interact in a precisely defined fashion and (b) a “*network-security architecture*” that addresses the overall network-security policy.

These concepts enable the architecture to evolve without having to go back to reassess the role of each individual component each time a deployment consistent with the architecture is changed. This also led to the ability to recursively “compose” a set of individual components into a new single logical component that has a well-defined role within the network-security architecture and a well understood composite security rating.

TCB subsets within a single system. The second strategy, the “incremental evaluation” or “subset evaluation” of a TCB was used by Gemini Computers to internally structure the TCB of its Gemini Trusted Network Processor (GTNP) and was first publicly presented in [21]. It builds on the idea that a complex TCB may be divided into simpler TCB subsets,

each of which enforces a subset of the global security policy. The effect of such security policy decomposition, when allocated to the various TCB subsets, is to allow for a chain of simpler evaluations (each an evaluation of a subset) to be performed, leading to an overall conclusion that the composite TCB is correct. Unlike a TCB consisting of multiple partitions, incrementally evaluated TCB subsets are thought of as residing in the same, tightly coupled processing component. The subset strategy is particularly well suited for TCBs that enforce relatively complex security policies over virtual objects that are very different from the physical storage objects provided by the processor hardware. For that reason, the TCB subset strategy is particularly appropriate for the application to trusted database management systems (DBMSs).

The partition and subset evaluation strategies are compatible, and may be combined in various ways for TCBs that are complex both in architecture and security policy. This has been proposed, for example, for an embedded secure DBMS [22].

Balanced assurance. As we have noted, there are fundamental differences between the degree of protection from malicious software offered by the enforcement of a mandatory security policy and that offered by enforcing a discretionary security policy. This difference has led to the development of a useful technique, called *balanced assurance*, for enhancing assurance in the parts of the TCB where it matters most.

Using partitions or subsets, one of two positions for assurance in a TCB can be adopted. The more conservative approach requires that all assurance requirements for a particular evaluation class must be applied uniformly to the entire TCB. This is termed *uniform assurance*. The less conservative position requires the application of assurances to partitions or subsets only where the assurances are relevant to the security policy enforced by the partition or subset and provide a genuine increase in the credibility of security policy enforcement. This approach is called *balanced assurance* [23]. Balanced assurance is typically used when there is relatively little risk from low assurance for those TCB subsets not enforcing or supporting the mandatory security policy. This means that where we have a high assurance for the partitions and subsets responsible for the mandatory security policy, we can have a high assurance in the overall security of a network that

contains partitions (e.g., enforcing DAC and audit) that only meet the lower requirements for assurance. Balanced assurance is an important practical technique for achieving near-term high assurance where it counts in complex systems facing a serious threat.

The assessments discussed above are focused on the ability (or inability) to state that a system is free of major security-impacting defects, i.e., what its vulnerabilities are. The importance of vulnerabilities to risk depend on the threat a system faces, and that is what we will address next.

Classification of Threats and Accepted Risks

Global dependence on computers is growing exponentially as is the value of information assets on computers. The presence of these assets increases the threat of attacks against computers, which in turn increases the risk. We can relate threat to risk with the following notional expression:

$$\text{Risk} = \text{Threat} \times \text{Vulnerability} \quad (1)$$

We distinguish these two elements, i.e., “threat” and “vulnerability” as follows:

- *Vulnerability* – a quality or characteristic of the computer system (e.g., a “flaw”) that provides the opportunity or means of exploitation.
- *Threat* – the possible existence of one who participates in the exploitation by gaining unauthorized disclosure or modification of information such as accompanies information-oriented computer misuse.

The weak security and plethora of vulnerabilities in today’s platforms generally reflects the environments and threats of 10–20 years ago, not the current environment or that expected in 5 years. For example, a decade or two ago, personal computers performed local processing of data in relatively closed environments – as their name implies they were for “personal” use. Today, there is growing demand for personal computing platforms to perform high-value business-to-business e-commerce over the Internet.

The large number of vulnerabilities of common computing platforms poses potentially calamitous risks to high-value business transactions. This is because not only are the computers themselves relied on to protect the data, but also because there is a growing threat that the vulnerabilities will be

exploited. The commercial transactions processed by these platforms are at risk, as is sensitive data accessed by these platforms such as that targeted by industrial espionage, organized crime, and state sponsored terrorism.

Table 1 below shows a range of four classes of threats, and some characteristics of those threats. The top half of the table represents planned, concerted attacks while the bottom half represents more casual attacks. We now summarize each of those classes of threat.

All entities are trusted to behave themselves – no TCB Needed. This represents the implicitly postulated threat for what we have termed *dedicated mode* where access is not enforced by the TCB. Any information protection that is afforded is provided on an *ad hoc* basis by applications, generally as an afterthought or incidental to the primary function of the application. There may be unintended access to information. This may lead to embarrassment or inconvenience, but no security policy is violated. The threat is simply human error that leads to disclosure or modification that is basically probabilistic in nature. Such threats may involve a combination of human, hardware, and timing factors that when combined could allow an unintended (with respect to the purpose of the application) disclosure/modification of information.

Simple examples of this are a user typing sensitive information into a file that is thought to be nonsensitive, or including an unintended recipient as an addressee for E-mail. Users receiving information from this kind of disclosure or modifying information in this manner are often victims of circumstances and may not be malicious in their intent. Of course,

Table 1 Threat taxonomy

Type of attack	Threat	Effort to exploit	Motive for attack
Planned	Trapdoors (subversion)	Concerted planning	High value
	Trojan horses	Moderate	Moderate value
<i>Ad hoc</i>	Obvious holes in mechanisms	Easy	Ego boost (low value)
	Application weakness	Very easy	Vandalism

a trusted user might violate that trust and engage in some act of vandalism. They will find that easy to do, but that is not a “computer security” problem, since the computer was never designed to control such actions of users or applications. This class of threat has limited motivation and is focused on exploiting properties of the application not designed to be relied upon to enforce a security policy. The consequences are commonly called *inadvertent disclosure* and predominantly result from accidentally occurring states in the system or from human error.

Direct Probing – No Mandatory TCB Expected.

We can use the term *probing* to distinguish this class of threat from that in the above case, where an individual uses a computer system in ways that are certainly allowed, but not necessarily intended, by the system’s operators or developers. It is important to realize that the individual who is attempting probing is deliberate in his attempts. This introduces a class of “user” that computer system designers may not have seriously considered. Often, designs reflect that the systems are expected to operate in a “benign environment” where attempts to violate the system controls are presumed to be accidental, or at least amateurish and *ad hoc*. This limited design attention is the situation with most commercial systems today that offer only discretionary controls, i.e., no enforcement of a MAC policy.

This represents the implicitly postulated threat for what we have termed the *system high mode*. Because systems are presumed to be in a relatively benign environment (i.e., not under professional attack), the attacker may not have to exert much effort to succeed. By benign, we mean that this threat is typically from an amateur attacker, not a professional. A professional attacker is distinguished from the amateur by objectives, resources, access, and time. The professional is concerned about avoiding detection, whereas, amateur attackers are often motivated by a desire for notoriety or simple curiosity, as much as for gaining access.

Most of the current publicity surrounding computer and network-security breaches represent the work of such amateurs and involves frontal attacks that exploit either poor system administration or the latest hole that is not yet patched. A successful attack is commonly called a *penetration*. The threat deliberately attempts to exploit an inadvertent, preexisting flaw in the system to bypass security controls. The

penetrator will exploit bugs or other flaws to bypass or disable system security mechanisms. To succeed, the penetrator must depend upon the existence of an exploitable flaw. These frontal attacks are inexpensive to mount, and akin to a mugger in a dark alley not knowing if his next victim has any money or worse, a gun. In contrast, a professional seeking big money is not likely to use such methods given the unknown payoff and chances of being caught. We look at two classes of those professional threats next.

Probing with Malicious Software – TCB for MAC is Needed.

A professional will be well funded and have adequate resources to research and test the attack in a closed environment to make its execution flawless and therefore less likely to attract attention. This is in sharp contrast to the above *ad hoc* threats. The professional attacker understands the system life cycle and may surreptitiously construct a subverted environment by injecting artifices [24], e.g., malicious software, while participating in or controlling the efforts of a development team. In a large system with complex dependencies between modules, the opportunities for this are abundant. The well-motivated attacker will invest and plan. A system identical to the target will be obtained so it can be prodded and probed without worrying about being accidentally noticed by an alert operator, or even firewalls or intrusion detection systems. Attack methods will be tested and perfected.

The target can expect the professional to be attracted by information of value. As noted earlier this implies a need for classifying the worth of the information, and using that data classification scheme as an integral part of a MAC policy. The astute system owner will recognize the need for a TCB designed to enforce this policy. In other words, such a system will typically be a candidate to be operated in what we termed *multilevel mode*.

Finally, the professional is willing to invest significant time in both the development of the artifice as well as its use, possibly waiting years before reaping the benefits of the subversion. The subverter (who plants the artifice) may be – in fact, usually will be – an individual who is different from the attacker. A professional may have paid or persuaded someone else to perform the subversion and will at some point in the future, activate the artifice and attack the system. This may provide the professional attacker with a degree of plausible deniability not possible

with typical frontal attacks. For a state sponsored or other professional adversary such deniability is highly desirable.

The malicious software of this class of threat is termed a *Trojan horse*. The term *Trojan horse* for software is widely attributed [9] to Daniel Edwards, an early computer security pioneer, and it has become standard term in computer security. As with its mythological counterpart, it signifies a technique for attacking a system from within, rather than staging a frontal assault on well-maintained barriers; however, it does so without circumventing normal system controls. A Trojan horse is a program whose execution results in undesired side effects, generally unanticipated by the user.

A Trojan horse will most often appear to provide some desired or “normal” function. In other words, a Trojan horse will generally have both an overt function – to serve as a lure to attract the program into use by an unsuspecting user – and a covert function to perform clandestine activities. Because these programs are executing on behalf of the user, they assume all access privileges that the user has. This allows the covert function access to any information that is available to the user. The covert function is exercised concurrently with the lure function. This is essentially what the more sophisticated recent viruses do. This is a particularly effective option for the attacker owing to the fact that an authorized user is tricked into introducing the Trojan horse into the system and executing it. As far as any internal protection mechanism of the computer system is concerned there is no “illegal” actions in progress, so this type of attack largely eliminates the attacker’s exposure to discovery.

Subversion of Security Mechanism – Verifiable TCB is Needed. The final class of threat also uses malicious software in a planned professional attack, but uses it to subvert the very security mechanism itself. The distinction between a Trojan horse and this artifice as used in system subversion is important. The Trojan horse provides a function that entices the victim to use the software as well as a hidden function that carries out the malicious intentions of its designer. With the Trojan horse technique, system security mechanisms are still in place and functioning properly – the attacker’s code is executed with and limited by a legitimate user’s access permissions. In contrast, subversion does not

require action by a legitimate user. It bypasses any security mechanisms that the subverter chooses to avoid. The most common forms of artifices used in subversion are known as *trapdoors* [5].

Subversion of a computer system’s security mechanism involves the covert and methodical undermining of internal system controls to allow unauthorized and undetected access to information within the computer system. Such subversion is not limited to on-site operations, as in the case of deliberate penetration. It includes opportunities that spread over the entire life cycle of a computer system, including (a) design, (b) implementation, (c) distribution, (d) installation, and (e) use. The subverter is not an amateur. To be able to carry out subversive operations, the subverter must understand the activities that are performed during the various phases of a computer system’s life cycle. But none of these activities are beyond the skill range of the average undergraduate computer science major.

Recently, the “two-card loader” has gained notoriety. The two-card loader is named after the main-frame loader that was punched into two cards (too large to fit on one card). The hardware reads the two loader cards into a well-known location in memory, then transfers control to the first line of the loader program. The loader program, in turn, reads in the rest of the card deck and transfers control to the program contained therein.

A two-card loader subversion of an operating system reads in a malicious program as data, then transfers control to it. If a two-card loader is hidden in a commercial (or open source) operating system, then it can lie silently waiting for its trigger before doing its single, very simple job. A geek cannot find a well-written two-card loader. Exemplar subversions with a six-line “toehold” have been demonstrated [25], whereas Microsoft was unable to find an entire video game hidden in Excel before release.

Finally, a subversive artifice will typically include the capability of activation and deactivation. It was recognized long ago [3], based on experience with information warfare demonstrations, that “deliberate flaws are dormant until activated by an attacker. These errors can be placed virtually anywhere and are carefully designed to escape detection.” The artifice activation mechanism waits for the presence of some unique trigger. Examples are a particular stack state, an unlikely sequence of system calls or signals, or codes hidden in unused portions of data

structures passed into the kernel via system calls. The possibilities are endless. This trigger can be thought of as a key that can be made arbitrarily long from a cryptographic standpoint.

Security Evaluation Criteria Standards

The pervasive dependence on computers today gives us no choice, but to use them in the face of a threat from professional attackers. To responsibly manage the risk, we must not only create computers that are secure, but also verify that we have succeeded. It is essential that we have criteria for computer security evaluation.

If a platform is to withstand a planned hostile attack, a high degree of assurance in the security mechanism is required. Having the best technology in the world is of little value unless customers can know it has been effectively applied to their selected platform. Customers are often surprised at how hard that is, because of the general experience that through testing they can determine compliance in almost all areas of information technology. Unfortunately, testing is rather useless for demonstrating the security of a platform – as noted earlier, testing can only demonstrate the lack of security by exposing specific flaws. Simply offering a platform, with an absence of those specific known flaws, does not satisfy the customer's need for measurable trust.

Thirty years ago, the military identified that the greatest risks came when security tests of systems (e.g., “penetrate and patch”) found no flaws. Managers responsible for assessing risk become tempted to trust such systems despite a lack of real evidence of trustworthiness. Alternatively, citing standards and practices, e.g., of an industry alliance, may sound impressive, but does not suitably measure trust unless the standards and practices are proven and sound, and compliance is confirmed. Customers need products that are evaluated by objective third parties against proven criteria. Fortunately, various bodies, including European and US governments, have long recognized the need for standard security criteria. The resulting evaluation criteria have been evolving and have been used for over twenty years to evaluate numerous commercial products. The results of this evolution for risk assessment have been mixed, with some of the most powerful evaluation technology largely unused.

This historical evolution of security evaluation criteria has generally been along two paths that

we review below: system criteria and component criteria. The primary thread for system security has been around the TCSEC [7]. As system criteria, a range of systems issues have been integral to its use, such as secure composition and maintenance of security over the life cycle. The primary thread for component (or subsystem) evaluation has evolved to the common criteria [26]. This provides a framework for evaluations that do not necessarily answer the question “is the system secure”.

System Criteria (TCSEC)

As outlined earlier, the only known way to substantially address the threat of subversion is verifiable protection in a TCB that implements the reference monitor in a security kernel. Initially, the efforts to develop system evaluation criteria made no assumptions about the methods of the attacker. It was assumed that threat included professional attacks such as malicious software subversion. Therefore, in the early efforts the criteria for a system to be “secure” were synonymous with what later became the high end of the range of assurance levels in the TCSEC, which it called *Class A1*. Only later in the process was it asked if there were any values in defining lesser levels of assurance.

Historically, in 1977, the DoD Computer Security Initiative began, and an effort was made to consolidate the R&D gains in the theory of computer security that we have already outlined. In 1981, the DoD Computer Security Center was formed to focus DoD efforts to evaluate computer security. In 1983, following about 6 years of work by the DoD with the National Bureau of Standards (NBS), the center published the TCSEC [27]. It was published only after working examples of products meeting each requirement existed and after being “. . . subjected to much peer review and constructive technical criticism from the DoD, industrial research and development organizations, universities, and computer manufacturers” [27].

The center's charter was soon broadened, and the National Computer Security Center (NCSC) was established in 1985. The NCSC oversaw minor changes to the TCSEC, and it was established as a DoD standard in 1985 [7]. These evaluation criteria deal with trusted computer systems, which contain a TCB. The focus on *system* security was clear. The initial issue of the TCSEC explicitly states, “The

scope of these criteria is to be applied to the set of components comprising a trusted system, and is not necessarily to be applied to each system component individually [27].” It also emphasizes, “the strength of the reference monitor is such that most of the components can be completely untrusted.” The trusted components to be evaluated are the TCB.

The criteria are structured into seven distinct “evaluation classes”. These represent progressive increments in the confidence one may have in the security enforcement, and each increment is intended to reduce the risk taken by using that class of system to protect sensitive information. These increments are intended to be cumulative in the sense that each includes all the requirements of the previous. The classes and their names are:

- Class D: minimal protection
- Class C1: discretionary security
- Class C2: controlled access
- Class B1: labeled security
- Class B2: structured
- Class B3: security domains
- Class A1: verified design.

The seven classes are divided into four divisions, termed D, C, B, and A. The structure of the divisions reflects the threats they are intended to address. Division A of the TCSEC makes no assumptions about limiting the attacker. Division B hypothesizes that the attacker can subvert the applications, but not the operating system. Division C hypothesizes that the attacker uses no subversion at all. And, division D assumes that customers believe that attackers believe the vendor marketing claims. Notice that these threats correspond directly to the four classes of threat

we addressed in the section titled “Classification of Threats”. Only division A, called *verified protection*, is intended to substantially deal with the problems of subversion of security mechanism. This is shown in Table 2, which is essentially Table 1 augmented to include needed assurance.

Following initial publications of the TCSEC, the NCSC developed a number of interpretations and guidelines that assist in applying the principles of the TCSEC. These are collectively referred to as the *rainbow* series, because of their various cover colors. The TCSEC itself was commonly referred to as the *Orange Book*. One of the important topics of this series is composition.

Composition Criteria (Networks, Databases, Modules)

Commercial evaluations under the TCSEC made available trusted systems whose security properties were independently evaluated. However, there were two real-world concerns that motivated published interpretations of the TCSEC dealing with composition:

- the ability to enforce a variety of system security policies at varying levels of assurance; and,
- the ability to incrementally evaluate networks and systems based on well-defined modifications (e.g., the addition of a new subnetwork).

The initial systems evaluated were stand-alone computers, so some inaccurately assumed that use of the TCSEC was limited such that it could not be applied to a network of computers or layered applications, such as DBMSs, with their own security

Table 2 Platform trustworthiness needed to counter threats

Type of attack	Threat	Effort to exploit	Motive for attack	Assurance needed to counter
Planned	Trapdoors (subversion)	Concerted planning	High value	Division A
	Trojan horses	Moderate	Moderate value	Division B
<i>Ad hoc</i>	Obvious holes in mechanisms	Easy	Ego boost (low value)	Division C
	Application weakness	Very easy	Vandalism	Division D

policies. Since the TCSEC provides complete and reasonable criteria for evaluating systems (not just component), including networks as noted in [28] and [29], explicit interpretations and guidelines were published.

Networks. The section titled “Objectives of Assessments” has identified the major components in the strategy for a “partition evaluation” of a trusted network of independent, loosely coupled, intercommunicating processing components. The partition evaluation strategy was first introduced in [30]. It is the basis for Appendices A and B of the Trusted Network Interpretation (TNI) [18], which provides interpretations for the application of the TCSEC to networks. The TNI imposes the context of a “network-security architecture” that permits components of systems to be individually evaluated in a way that ensures that the eventual composition of the overall system will be secure.

A commercial example was the evaluation of Novell’s NetWare network under the TNI. Novell desired an evaluated system, yet was not in the business of building clients. They faced the question of how to specify the role of the client such that other vendors could produce clients that would be secure within the Novell network-security architecture. Novell completed three distinct but related evaluations: client; server; and network [31].

Balanced Assurance. The TNI Appendix A endorses the use of balanced assurance (though not by name) through its stipulation of a maximum class of C2 (with respect to assurance) for those TCB partitions not enforcing or supporting the mandatory security policy. Consistent with our earlier description of balanced assurance, this means that one can have a Class A1 network that contains partitions (e.g., enforcing DAC and audit) that only meet the Class C2 requirements for assurance.

Layered Applications. The initial focus was on developing an interpretation for a trusted DBMS. The final draft agreed to by the drafting working group of area experts recognized that the concepts applied to “extensions of the TCBs for applications that may need to provide access controls tailored to the specific design of the application subsystem as a whole”. This document [32] provided substantial rationale and

exposition of the underlying “TCB subset” concept. This is the basis for the “incremental evaluation” strategy identified in the section titled “Objectives of Assessments”. A significantly abbreviated version was published as the Trusted Database Interpretation (TDI) of the TCSEC [33], which provides interpretations for the application of the TCSEC to database DBMSs and other complex applications.

A delivered, commercial example of this was Trusted Oracle that was structured to exploit the properties of TCB subsetting. It included a mode whereby the MACs of the database were enforced by the mechanisms of the underlying operating system. This “evaluation by parts” solved the seemingly difficult problem of achieving a Class A1 database system, when neither the database vendor nor the operating system vendor was willing to provide the other with the proprietary evaluation evidence that would be necessary for a single system evaluation.

Ratings Maintenance Phase (RAMP). When changes are made to the TCB, its evaluation has to be reaccomplished. Using the TNI and TDI, it was clear that when the security architecture does not change, only the changed component, not the entire system, had to be reevaluated. This greatly simplifies maintaining the rating of the entire system. Similarly, when only selected modules internal to the TCB of a single component are changed, it should be possible to simplify the reevaluation. One of the most common and important internal changes is upgrading to new hardware as the technology changes, e.g., upgrading from a motherboard with an Intel 286 16-bit processor to an Intel Pentium 32-bit processor.

The NCSC put in place a codified rating maintenance phase (RAMP) process, so the vendor did not have to start over. The goal of evaluation is to put “secure” systems into the marketplace and into the field. With RAMP, the evaluation process served that goal, but did not supplant it. High-security systems are expensive to evaluate (tens of millions of dollars for an A1 system in the 1980s) and take a long time to evaluate (10 years from initiation to final evaluation). With RAMP, this can be reduced to a few months, or even weeks, so from the practical point of view, this is a critical tool for deploying secure systems.

Component Criteria (ITSEC, Common Criteria, FIPS 140)

After its publication, the DoD and other organizations in the United States used the TCSEC for security evaluations. In the meantime, some western European nations began developing different criteria – the Information Technology Security Evaluation Criteria (ITSEC). In 1990, a group of four nations – France, Germany, the Netherlands, and the United Kingdom – published the first draft. The draft criteria, while substantially influenced by the TCSEC, were significantly different in a number of areas [34]. Its most notable difference was that the ITSEC could be applied to components or subsystems that did not form systems.

However, its authors were insightful enough recognize the value of the TCSEC evaluation classes, and included in the ITSEC [35], an “Annex A” that defined five “functionality classes” F-C1, F-C2, F-B1, F-B2, and F-B3 that were derived from the TCSEC. These could be combined with their assurance levels E1, E2, E3, E4, E5, and E6 with the intent of expressing the same requirements as the TCSEC. For example, the criteria for “E6 F-B3” were intended to represent Class A1. In practice, several vendors at the lower assurance levels used the same evaluation evidence for evaluations in both the United States under the TCSEC and Europe under the ITSEC.

In the late 1990s, joint international efforts evolved a framework along the lines of the ITSEC into a new common criteria intended to replace both the TCSEC and the ITSEC. As with the ITSEC, common criteria evaluations need not provide a system context. The component or subsystem to be evaluated is called the *target of evaluation*. In general, evaluation of a subsystem may do the owner little good in terms of the risk to the systems, if overall system protection depends on software outside the target of evaluation. This can limit the value of a common criteria evaluation as a risk assessment tool, and the procurers of trusted systems may well have to perform much of the work of a TCSEC evaluation to do their own systems evaluation. As one example, a respected observer has pointed out [19]:

The Common Criteria does not include strong requirements for trusted distribution. Instead, it has a single delivery family, ALC DEL, which requires that a developer document procedures for delivery and use those procedures. Hence, the EAL levels do

not speak to trusted delivery at all. What one needs to prevent subversion of a high- or medium-security system is [Class] A1-style configuration management and trusted delivery.

In reality the common criteria is more of a metacriteria that provide a common language for expressing a particular criteria. It can be used to create what it defines as a “protection profile” that could come much closer to providing concrete criteria. Several security technologists and users have suggested a set of US government validated *protection profiles to mirror each of the TCSEC evaluation classes*, including the components defined in the TNI. This would be analogous to the “Annex A” of the ITSEC. So far, this suggestion for an explicit basis for applying the common criteria as a system criteria seems to have been actively resisted.

A similar challenge exists for standards for components or subsystems in other security related areas. For example, the application of cryptography has been greatly enhanced by standards such as FIPS 140-2 [36], which can make the engineering of cryptographic products like virtual private networks (VPNs) a lot more likely to be sound. Cryptography advances have indeed been considerable. However, current cryptographic products are mostly built on platforms having weak security. And, the recent neglect of the science of computer and network security suggests this will not be corrected in the near future.

As a result of this major weakness in cryptographic deployment, it has, in many cases, become what has been referred to as the *opiate of the naive*. This is not a unique insight of the authors, but has been noted by others as well. For example, one long-term expert noted [37]:

cryptography, in the form of digital signatures, public key certificates, and the like have become the “security architecture” for network based systems of the future. This trend totally ignores the fundamental fact that such encryption will only be as secure as the operating system structure in which it sits. . . . Contrary to accepted ideas, then, the use of cryptography actually enhances the need to reconsider security functionality and evaluation at the operating system and hardware levels. . . .

The common criteria and other component evaluation standards have led to a number of evaluated products, but a dearth of evaluable systems. A major contributing factor is that without something like the

suggested TCSEC/TNI equivalent protection profiles for the common criteria, there is no prescribed distinction between system evaluation and subsystem evaluations. This encourages the following:

- a willingness to make baseless assumptions about the behavior of “other” software subsystems, i.e., those falling outside the “target of evaluation”;
- a willingness to assume unenforceable prescriptions on the behavior of attackers;
- the classic logic error of treating all security policies as the same, and then concluding that certain techniques do not solve any of the problems because they fail to solve all of the problems. For example, because verifiable protection for MAC does not fully solve the problems of denial-of-service, some will overlook the fact that verifiable protection can control the risk from the procurement and deployment of a secure operating system that could be subject to subversion by a mortal enemy.

Toward Quantitative Risk Assessment

Over the past few decades, computer security has become an urgent need as computers have moved from tools for specialized use, to the dominant and essential component of the “information age”. Yet, even the casual observer would conclude that there are essentially no commercial operating systems in use today with adequate protection for information of significant value that are appropriate for use in environments where not all users are trusted (cleared) to see all information on the system. That being the case, *procurers and users would be well served by carefully assessing the risk* as part of their decision to make such deployments.

Dr David Bell, one of the most knowledgeable and experienced computer security professionals, shared this view when he recently painted [19] a bleak and alarming picture along the following lines. In today’s networks, MLS connections between networks are unavoidable. The threat of sophisticated attack or subversion makes low-security systems unacceptable for connections between isolated networks. High-security systems must be used. Very difficult computer- and network-security problems confront us today. This is best seen in the need for increased communication between different security domains and in the need

to reduce desktop clutter caused by separate workstations for each different security domain. Both of these situations call for high levels of security, both from a policy perspective and from first principles.

Dr Bell continues by noting that currently most of these critical needs are being filled by low-security components, whose deployments are contrary to security policy. Even in the absence of explicit policy, *such deployments are ill-advised, verging on irresponsible*. An attack on a weak connection no more sophisticated than the Cuckoo’s Egg [38] gives an attacker complete control. Subversion of a weak connection allows adversaries to mount attacks of their choice at any time in the future. Such attacks can steal information, alter critical information, or bring down computers, or entire networks. The worst subversion, called the *two-card loader*, cannot be prevented or even found in low-security systems [19]. Direct attacks like the Cuckoo’s Egg can only be thwarted by full mediation and self-protection, as required by B2/EAL5 or better systems. Complete prevention of subversion requires life-cycle security of the form found in Class A1 systems [19].

This state of affairs that he summarizes cries out for systematic risk assessment. Historically, computer security was viewed as a binary determination – either the system was verifiably secure, or its security was at best undecided (if not unknowable). This categorization did not come about immediately, but resulted from years of unsatisfactory attempts to use techniques like testing (e.g., “penetrate and patch”) to characterize the security of a system faced with professional adversaries. Quantitatively, the probability that commercial computer systems can be relied upon to enforce a coherent, logically complete security policy approaches zero.

In trying to quantify risk, it is tempting to try to quantify vulnerability. The above discussion indicates that most efforts to quantify vulnerabilities are not very promising. The reality of that is largely binary, and the primary uncertainty is the users awareness of vulnerabilities. It seems the implications have still not sunk in. Today, many still focus on how quickly the latest set of security “patches” is installed, when these responses to amateur attacks have little to do with the risk from serious threats, but rather with the awareness of specific vulnerabilities. There is little realistic expectation that serious vulnerability from things like maliciously installed trapdoors will show up on a patch list.

But, at the same time, it is useful to at least recognize that *data classification has moved toward quantitative risk assessment*. Recall that although quantifying vulnerability is difficult, one thing we noted that does bear distinguishing, is how “valuable” information is. This implies the need for “data classification”, which fortunately, in turn, directly supports a precise MAC policy. And we have already summarized the powerful theory for assessing the ability of a system to effectively enforce an MAC policy. Data may be classified numerically, as with a range of monetary values, or relatively, as the government classifying “secret” information as more valuable than “confidential” information. A number of sizable commercial enterprises have analogous classification schemes for sensitive data.

The use of this for risk assessment is illustrated by an example of how, in the past, the *US government quantitatively computed a risk index* when it used the TCSEC for computer security evaluation. The TCSEC was accompanied by a quantitatively framed policy [39] to guide users in selecting the minimum level of evaluation a system should meet. This defined a numerical “minimum user clearance or authorization ($R_{\min}$)” rating from 0 to 7 based on “the maximum clearance or authorization of the least cleared or authorized user.” It similarly defined a numerical “maximum data sensitivity ($R_{\max}$)” rating from 0 to 7 based on the value of the most sensitive

information being processed. It then computed the “risk index” which, in the simple case, was “determined by subtracting $R_{\min}$ from $R_{\max}$.” This was used to determine the “minimum security evaluation class” based on approximately what is represented in Table 3 below.

Although this is only an example, it shows how a technically sound evaluation scheme can be leverage for a systematic risk assessment.

The relationship between the TCSEC evaluation divisions and the threat is reflected in Figure 2 below. This figure also has a notional illustration of quantitative value to the user, of the various evaluation levels, with a rough correlation

Table 3 Minimum security class for risk index

Risk index	Minimum security class
0	C2
1	B1
2	B2
3	B3
4	A1
5–7	Beyond state of current technology

Figure 2 Cost and time to develop and evaluate trusted systems

between the TCSEC and common criteria evaluation levels.

In conclusion, we have seen that the theory of computer security is quite rich with solutions and tools. There is little reason that systematic risk assessment cannot effectively leverage the accumulated knowledge from research and practical experience of more than 30 years. The greatest past achievement of computer and network security is the demonstrated ability to build, and operationally deploy truly bulletproof systems having verifiable protection. This remains the most powerful solution available for many of today's hard computer problems.

Unfortunately, today many of those proven results for both developing and evaluating trusted systems languish and are unused. Risk assessment, as currently practiced, is largely in denial about the imminent and growing threat of professional attack using malicious software subversion, and also determinedly ignorant about the powerful technology that is available. The authors hope that the historical perspective summarized in this article will help rectify that.

End Notes

Condition Monitoring

Condition monitoring (CM) is a set of various techniques and procedures that people use in industry to measure the “parameters” (also called *features* or *indicators*) of the state/health of equipment, or to observe conditions under which the equipment is operating. The user’s main interest is in the equipment’s proper functioning (i.e., to operate as designed). The British Standards Institution Glossary gives a good and concise definition of CM: “The continuous or periodic measurement and interpretation of data to indicate the condition of an item to determine the need for maintenance” (BS 3811: 1993). CM is mainly applied for early detection of signs of malfunctioning and faults, and then for faults diagnosis and timely corrective or predictive maintenance. CM is also applied for operation/process control (e.g., to signal a jam on an assembly line and/or to stop the process), or safety control (checking the closure of a machine’s safety door) with a primary goal to prevent or reduce consequences of failures. Two common examples of CM are vibration analysis of rotating machines (e.g., centrifugal pumps, or electrical motors) and oil analysis of combustion engines (analysis of metal particles and contaminants in the lubrication oil), transmissions, and hydraulic systems. The whole combination of CM data acquisition, processing, interpretation, fault detection, and maintenance strategy is often called *CM system/program* (alternatively, *condition-based maintenance* (CBM)). The British Standards Institution Glossary’s definition of CBM is “Maintenance carried out according to need as indicated by condition monitoring”. An ideal situation would be to monitor conditions of all elements/parts of the machine, or, at least the ones most likely to develop significant problems. Complete monitoring is usually not possible technically, or is expensive, and it is thus important to select parts/elements of the system to monitor, and also select a method of monitoring. Common criteria for selection are based on experience and past information about failure modes and their frequencies, consequences of failures, such as downtime and cost, lost production, low quality of products, and so on, and availability of appropriate techniques. The main purposes of implementing a CM system are to be cost-effective by optimizing the maintenance program, and/or to avoid the

consequences of inadequate functioning and failures. CM is either an “off-line” procedure, when measurements/samples are taken and analyzed at predetermined moments of time (or when convenient), or an “on-line” procedure when the measurements are taken (and often analyzed) continuously, or at short intervals by the sensors permanently mounted on the equipment. Often, CM is a combination of various off-line and on-line procedures. A typical example of an off-line procedure is oil analysis, and of an on-line procedure is vibration analysis. Vibration monitoring is still commonly used as an “off-line” technique if the equipment deteriorates gradually. Now, due to advanced technology, oil analysis can, for some cases, be applied on-line (e.g., using wear debris light detectors).

The most common CM techniques/methods are vibration analysis, tribology (oil/debris analysis), visual inspections, current monitoring, conductivity testing, performance (process parameters) monitoring, thermal monitoring, corrosion monitoring, and acoustic (sound/noise) monitoring.

Monitored parameters/features can be direct, such as thickness (e.g., for brakes), amount of wear, corrosion, or cracks; or indirect, such as pressure, temperature, efficiency, vibration, and infrared and ultrasound images; or others, such as operating age. The parameters could also be operational (pressure, temperature, flow rate etc.), or diagnostic (vibration, amount and/or shape of metal particles in oil, water content in oil). Note that parameters/features are aggregated CM indicators calculated from collected raw CM data.

The methods of data/equipment condition assessment can be simple, such as measurement value checking, trending against time, or comparison with templates. They can be more advanced, such as mathematical models of deterioration and risk of failure, and artificial intelligence (AI) methods, such as neural networks and expert systems (ES).

Instruments/sensors for CM data collection/acquisition could be portable or mounted. Some instruments originated long time ago, such as temperature sensors, stroboscope (1830s), and piezoelectric accelerometer (1920s). Some instruments are more recent, such as fiber-optic laser-diode-based displacement sensors (late 1970s), laser counters combined with image analysis technology, or on-line transducers for wear particle analysis (1991). A lot of new instruments, now in use, have implemented software

for data processing, analysis, display, or wireless storage into a database.

Short History of Condition Monitoring

The development of CM technology was closely connected with the development of electronic instruments, transducers, microprocessor technology, software, mathematical modeling, and maintenance strategies. Following [1], the history of CM after its initial steps may be briefly separated into the following four stages: (a) From the 1960s to the mid-1970s, simple methods were used, combining practical experience and elementary instrumentation. (b) In the 1970s, the development of analog instrumentation was combined with the development of mainframe computers. At that time, clumsy vibrometers came into practice to measure and record vibration. Tape recorders were used to transfer data to computers, where the data was analyzed and interpreted. (c) From the late 1970s to the early 1980s, rapid development of microprocessors made possible development of much more convenient digital instrumentation which was able to collect the data, analyze it, and store the results. (d) In the mid-1980s, instruments became much smaller, faster, and the data was routinely stored on PCs for long-term use and development of maintenance strategies. Using CM was still a choice of advanced companies. Now, every more sophisticated piece of equipment arrives with built-in sensors/monitoring devices, and capability for data analysis, problem diagnosis, warning, and even maintenance recommendation. An everyday example is a new model of the private automobile.

Combination of emerging CM techniques, development of mathematical reliability methods, and new approaches to maintenance resulted in the development of new CM strategies. Initially, people predominantly used failure (breakdown/corrective)-based maintenance. Then people started using preventive (time-based) maintenance, and then, with introduction of CM methods, predictive maintenance (or CBM). This now resulted in many sophisticated and effective (but sometimes expensive) CM systems.

Implementation of Condition Monitoring

People usually apply CM to systems where faults and problems develop gradually, so they are able to

make timely maintenance decisions, such as (a) to stop the operation immediately (due to an imminent failure with significant consequences), (b) to stop at the closest convenient time (at the next planned shutdown), (c) to continue normal operation up to the next planned monitoring, without any particular action. People use collected CM data, also for the following: (a) prediction of CM parameters/features and estimation of remaining operating life, (b) long-term planning of further maintenance activities and need for spare parts, (c) fault detection and diagnostics. The obvious advantages of using CM are to be in much better control of operation, timely prediction of problems, reduction in downtime, reduction in maintenance costs, planning of activities, etc. Problems related to CM could be: difficulty to select an appropriate CM technique, possibility of high initial capital investment in instrumentation, implementation and education of personnel, necessity of standardized data collection, storage, analysis, and application of results, etc. Often, CM methods cannot provide very reliable results, and then engineers prefer to use their own judgment in combination with CM. CM may have only marginal benefits, particularly if applied to noncritical equipment, or applied with an inappropriate technique.

Basic Steps in Implementation and Use of CM Systems

The basic steps in CM implementation are as follows: (a) identification of critical equipment or systems, (b) selection of an appropriate technique/combination of techniques, (c) implementation of the technique (installation of instrumentation, setting baselines/alerts, and diagnostics), (d) data acquisition and processing, conditions assessment, and if necessary fault diagnostics and equipment repair, and (e) CM system review and adjustment after certain time. Selection of a CM system depends on several criteria, such as on the level of known relationship between the parameters and the conditions of the equipment, the ability of the system to provide timely warning of problems or deterioration, the availability of historical data and predefined and absolute standards for the assessment of equipment condition and fault diagnostics, and on the benefit of CM over an existing strategy.

An example of a CM implementation to the oil pump supplying a gas turbine (see [1]):

Main failure modes

Bearing, coupling or impeller wear, oil seal failures (possibly due to misalignment), out of balance, cavitation, overload, lack of lubrication or supply restriction.

Warning signs

Changes in vibration, temperature, current and performance (measured as pressures or flows), visible signs of leak.

Most critical failures

Bearing failure; damage could be significant.

Least critical failures

Oil leak and cavitation; no immediate risk.

CM techniques

Vibration analysis (prediction of failures caused by imbalance, misalignment, cavitation, wear, and lack of lubrication), general inspection (looking for leaks, noise, and changes in pump performance).

Setting up CM

Select and mark the measurement locations on the pump. Take monthly vibration readings on all motor and pump bearings, and on casing. In case of first warning signs, take readings more often. Set alarm and warning levels.

Reviewing

Review alarm and warning levels to optimize balance between failure consequences and excessive maintenance. Review regular measurement interval to decrease or increase it. Review usefulness of the whole CM system after a certain period of time by checking reduction in failure frequency, pump performance, increase/decrease in maintenance efforts, and cost-benefits.

More Details on Key Steps in CM Systems/Programs

The three major steps in a CM system are data acquisition, data processing, and data assessment in combination with decision making.

Data Acquisition (Data Information Collecting)

Data can be obtained from various sources, either by monitoring direct (thickness) or indirect (pressure, efficiency, vibration, cumulative stress parameters)

state parameters, and by using various CM techniques and instrumentation/sensors. Methods of data acquisition are local inspections, local instrumentation, process computers, portable monitoring equipment, and built-in monitoring equipment/sensors.

The most common CM techniques are as follows:

Vibration analysis (the most used and most convenient technique for on-line CM in industry today; intends to predict imbalance, eccentricity, looseness, misalignment, wear/damage, and so on).

Temperature analysis (monitoring of operational/surface temperature emission – that is, infrared energy sources using optical pyrometers, thermocouples, thermography, resistance thermometers).

Tribology (oil/wear debris analysis of the lubricating and hydraulic oil).

Performance/process parameters monitoring (measuring operating efficiency; possibly the most serious limiting factor in production).

Visual/aural inspections (visual signs of problems by a trained eye, such as overheating, leaks, noise, smell, decay; video surveillance of operation, utilization of visual instruments; these methods are usually cheap and easy to implement).

Others techniques, such as current monitoring, conductivity testing, corrosion monitoring, and acoustic (sound/noise) monitoring.

Data Processing

In the data processing step, the acquired raw CM data is validated and then transformed to a convenient form. After validation, the data may be either used in a raw form, such as from temperature, pressure, number and form of metal particles in oil, or in a transformed form (from vibration data, thermal images, and acoustic data). The data can be collected as a direct value (*value type*) of the measured parameter (oil data, temperature, and performance parameter), a time series (*waveform type*), where one measurement consists of information from a (usually short) time interval (vibration, acoustic data), and space-specific (*multidimension type*), where one measurement collects information over an area or volume (visual images, infrared thermographs, X-ray images, and ultrasound images). The *value type data* is either used directly, or some simple transformations is applied to it, such as rates of change, cumulative values, ratios between different variables, and

various performance measures and health indicators. The raw waveform and multidimension type data is always transformed (a procedure called *signal processing* or *feature/parameter extraction*) into a form convenient for diagnostic and prognostic purposes. The *multidimension type data* is most often transformed into plain images (infrared photo), or into some overall features of the image, such as density of points. The *waveform type data* is processed in time domain, frequency domain, or combined time–frequency domain. Some overall characteristics of the raw signal (e.g., vibration) are calculated in time domain, such as the mean, peak, peak-to-pick, standard deviation, crest factor, skewness, and kurtosis. In frequency domain, the contribution of different waves to the whole signal is analyzed (characterized by their frequencies and “weights” – amplitudes). A typical method of signal processing is to use frequency analysis (called *spectral analysis* or *vibration signature analysis*) by applying the Fast Fourier Transform (FFT) to the signal to calculate power spectrum. The overall measures of the spectrum are then used (overall root mean square (RMS)), as well as the measures of different frequency bands. Different frequency bands are indicative of different failure modes, or problems with different components of the system. This feature of the vibration signal is one which makes the vibration analysis the most popular of all CM techniques. The analysis must be adjusted to the operating conditions, notably to revolution per minute (RPM) for rotating machinery. For example, the changes of amplitudes in the frequency band of $1 \times \text{RPM}$ may be indicative of motor imbalance, and in $2 \times \text{RPM}$ that of mechanical looseness. In combined time–frequency domain, time and frequency characteristics of the signal are analyzed simultaneously using joint time–frequency distributions, or more advanced methods such as wavelet transforms.

Data Management and Interpretation and Use in Decision Support

The final step in a CM system is the analysis and interpretation of the extracted parameters. The parameters can be used for *on-line decisions*, as described in the implementation section above, for *fault diagnostics* (see **Fault Detection and Diagnosis**) (detection, isolation, and identifications of faults when they

occur), and for *prognostics* (see **Reliability Integrated Engineering Using Physics of Failure**) (prediction of time and type of potential faults).

Fault Diagnostics. For fault diagnostics, people use various statistical methods (statistical process control (SPC), pattern recognition, cluster analysis), system parameters, and AI methods. The most common method for on-line fault detection is to use *signal levels* for monitored parameters, that is, predetermined control values (such as in oil analysis and vibration). This method falls into the category of SPC that originates from statistical quality control. Typical signal levels are selected to show normal state, warning state, and alarming state of operation. Different parameters should be indicative of different problems, e.g., in oil analysis depending on metallurgy of components, or in vibration analysis depending on vibration frequencies of different parts. The signal levels are established either by manufacturer’s recommendations, or from theory, or found by experience and experimentation. The other possibility is to use *pattern recognition*, when a suitable parameter is recorded over time and compared with templates for normal operation and different faults, often using some methods of automatic recognition. The *system parameters* method is used when the system can be described by a mathematical model with system parameters being directly related to system conditions. The template (or *normal*) parameters of the system are estimated from the past data of healthy systems. Changes in current parameter values indicate changes in system conditions and/or development of certain faults. AI (see **Scenario-Based Risk Management and Simulation Optimization; Risk in Credit Granting and Lending Decisions: Credit Scoring**) methods are used for fault diagnostics, particularly in larger and more complicated systems. These include artificial neural networks (ANNs), fuzzy logic systems (FLS) (see **Early Warning Systems (EWSs) for Predicting Financial Crisis**) ES (see **Uncertainty Analysis and Dependence Modeling; Probabilistic Risk Assessment**), case-based reasoning (CBR), and other emerging techniques. The application of AI in fault diagnostics and other areas of CM plays a leading role in the development of intelligent manufacturing systems (IMS), which are now increasingly in use. Practical applications of AI methods are still not widespread due to the need for large amounts of past data (measurement and

faults histories) and qualified judgments from experts required for system training.

Prognostics. *Prognostics* use past and current CM data to predict the future behavior of the equipment by forecasting parameters/features, or estimating remaining useful life (RUL—expected useful life). Also, estimation of the probability of failure before the next inspection is of great interest, particularly when safety issues are important (e.g., in the nuclear industry). The main methods for prognostics are, as for fault diagnostics, statistical, model-based, and those based on AI. Of the statistical methods, *trending* is the most popular and simple method. The users extrapolate current and past measurements of parameters (e.g., using linear, or exponential trends) to predict when the parameters will cross warning (or alarm limits) to be able to prepare remedial actions. This method works well when measurements show clear, monotonic trend, but is less useful when measurements show large variations (for example, in oil analysis, from the authors' experience). Mathematical models of risk in the form of *hazard function* or *risk of failure* are a useful tool for risk prediction. Hazard function is particularly useful for short-term risk predictions when it includes operating time and measurements (often called *covariates* in this area), e.g., in a form of proportional-hazards model (PHM). It is also useful for long-term predictions of probability of failure and RUL when combined with a dynamic probabilistic model for parameters. The current hazard value can also be successfully used as a decision variable by comparison with warning/alarming hazard levels. *Model-based* methods use a mathematical model for the equipment's operation in time on the basis of its structure, physical properties, and measurements (e.g., Kalman filter (*see Nonlife Loss Reserving*) for wear prediction, or prediction of fatigue crack dynamics). The risk-based and model-based methods are often combined with economic consequences for optimization of maintenance activities.

Final Comments and Recommended Readings

The rapid development and widespread use of CM can be easily observed from the Internet. A search for *condition monitor* (industry) in product category

results showed 50 categories of products with about 7000 companies and products. For example, the category *Machine and Process Monitors and CM Systems* listed 214 companies, 148 for *CM and Machine Maintenance Services*, 706 for *Non-destructive testing (NDT)*, and 34 for *Oil Sensors/Analyzers*. Following [2], the *next generation of CM systems* are likely to focus on continuous monitoring and automatic diagnostic and prognostics, and thus on the design of intelligent devices (e.g., micro-electro-mechanical systems technology), which will be able to monitor their own health using on-line data acquisition, signal processing and diagnostics tools.

Suggested reading for a quick introduction to CM and CBM are [1, 3, 4]. For more information, see [5–7] (mostly on vibration) and [8]. Practical guides and overviews of CM techniques and instrumentation (though some of the instrumentation information is out of date) are [9, 10]. A good introduction to multiple sensor data fusion is [11]. For a more advanced introduction to model-based fault diagnostics see [12]. Various practical implementations of CM can be found in the previous references, and also in [13]. For an overview of AI methods with some applications, see [14]. A good introductory *review article* of CM, with application to machine tools, is [15]. For a detailed overview of CM data processing, diagnostics and prognostics, see [2], and for applications of PHM in CM, see [16]. For an overview of the *history* of CM (with emphasis on vibration analysis), see [17].

Conflicts, Choices, and Solutions: Informing Risky Choices

In managing risky activities, decision makers (DMs) may have different available choices, payoffs or utilities (*see Utility Function*) for outcomes, as well as cultural expectations and ethical or moral values constraining how they believe they should behave. For example, a confrontation occurs in an international forum, such as in the development of certain terms for a convention or a treaty, where some stakeholders want to determine their best payoff, while minimizing that of another, before or during their negotiations (*see Considerations in Planning for Successful Risk Communication; Role of Risk Communication in a Comprehensive Risk Management Approach*). Similarly, an industry may assess what it can pay, before a fee or penalty schedule is codified. In these and many other situations, it is advantageous to describe alternatives or choices; positive or negative outcomes associated with each choice; probable effects of each choice, modeled by evaluating the probable consequences of different combinations of choices made by the DMs or stakeholders. The study of strategies and counterstrategies clarifies what a *solution* to a conflict (or partial conflict) situation is, when one exists, whether it is unique, why and whether it is stable (so that it is not plausible for players to deviate from it), conditions under which communicating with an opponent is or is not advisable, and ways to systematically change assumptions to test the sensitivity of results to those changes.

This article deals with key aspects of decisions by one or two stakeholders that confront alternative choices. In this confrontation, a *strategy* is a feasible act or option (including decision rules specifying what to do contingent upon information available at the time a choice must be made). Each stakeholder is assumed to have a discrete set of possible strategies that are mutually exclusive and fully exhaustive; these strategy sets are assumed to be common knowledge. A measure of value associated with each outcome is the *payoff* that each of the individuals has. Payoffs can be measured in units of money (usually transferable), *utility* (not necessarily transferable among players), or physical units (e.g.,

number of deaths or life-years lost), depending on the application.

Framework for Analysis

A Decision Maker with a Single Objective

Table 1 shows a problem with three mutually exclusive and collectively exhaustive choices (the rows) that a single DM must choose from. However, *Nature* – representing all factors over which the DM has no control – may affect the net gains or losses (in the cells of the table, the c_{ij}) by either taking on state 1 (s_1) or state 2 (s_2), with probability 0.50 each in this example. Note that the two states are mutually exclusive and collectively exhaustive: exactly one occurs. We can account for uncertainty by assigning probabilities to each of these two states, perhaps using historical data or expert judgment. The last column of Table 1 shows the calculation of the expected values of the acts/rows (defined by adding the values for each possible outcome, weighted by their respective probabilities). According to these calculations, a single DM who seeks to maximize expected value should choose act a_2 .

Before making a final choice, it is useful to measure the value of payoffs that might result from each choice. One obvious choice of scale is money. Another is *von-Neumann–Morgenstern (NM) utility*, which justifies the use of expected values (i.e., expected utilities) to choose among acts.

Two or More Decision Makers with Different Objectives

To depict a situation in which parties confront each other, one can replace “Nature” in the preceding example by a second rational, deliberating player. Options and payoffs for each player can still be tabulated. For example, here is a 3×2 , read *three-by-two*, representation (a matrix) of a hypothetical confrontation between two players, imaginatively called *Row* and *Column* (*blue* and *red* are also often used, especially in military applications).

	c_1	c_2
r_1	4	1
r_2	5	4
r_3	2	3

Table 1 Representation of choices affected by a neutral antagonist called *Nature*

Decision maker's alternative actions	States of Nature		Expected values
	s_1 (pr = 0.50)	s_2 (pr = 0.50)	
No action, a_1	$c_{11} = 200$	$c_{12} = -180$	$(0.5)(200) + (0.5)(-180) = 10$
Low cost intervention, a_2	$c_{21} = 100$	$c_{22} = -20$	$(0.5)(100) + (0.5)(-20) = 40$
High cost intervention, a_3	$c_{31} = 0$	$c_{32} = 0$	$(0.5)(0) + (0.5)(0) = 0$

The table shows Row's payoffs, measured in some units, such as dollars or utilities. If Row chooses the first row and Column chooses the first column, then Row receives a payoff of four units. In this type of zero-sum game, whatever Row wins, Column loses (and *vice versa*); thus, Row prefers large numbers and Column prefers small ones.

The largest of the row minima (*maximin*) is 4, and the smallest of the column maxima (*minimax*) is also 4: thus, the pair of choices (r_2, c_2) has the property that neither player can do better by deviating from (i.e., unilaterally choosing a different act from) this pair. The fact that the minimax (also called the *security level* for a player) and the maximin are the same identifies a "saddle point" solution (since, like the lowest point on the long axis of a saddle-shaped surface this point is simultaneously a minimum in one direction – it is the smallest payoff in row r_2 , and hence the smallest one that Column can get when Row selects r_2 – but is a maximum in the other (largest number in its column, and hence is the largest number that Row can achieve when Column selects c_2)). This is the "best" solution for both players, in the sense that neither can obtain a preferred payoff by a unilateral change of strategy (i.e., Row cannot do better by choosing a different row; and Column cannot do better by choosing a different column.) The celebrated minimax theorem [1] shows that any zero-sum game has a saddle point solution, provided that players are able to choose among alternative acts using any desired set of probabilities. In many practical situations, however, there is no saddle point among "pure" (nonrandomized) strategies. For example, consider the following 2×2 zero-sum game:

	c_1	c_2
r_1	2	-3
r_2	0	3

Because the minimax differs from the maximin, this game does not have a saddle point among pure

strategies. Further, no strategy dominates the other for either player (i.e., no strategy yields a preferred payoff for all choices that the other player could make). Nonetheless, if payoffs are measured using NM utilities, then a minimax strategy necessarily exists among mixed strategies.

Numerical solution techniques for zero-sum games (e.g., linear programming for general zero-sum games (Luce and Raiffa [2, Appendix 5]), Brown's method of fictitious play (Luce and Raiffa [2, Appendix A6.9]), the method of *oddmments* (Straffin [3] and Williams [4]), and various geometric methods) are well developed. For the game,

	c_1	c_2
r_1	2	-3
r_2	0	3

a simple geometric technique suffices: the two payoff lines represent Row's optimal probabilities for mixed strategy. The approach is depicted in Figure 1, as seen by Row, where the vertical axes measure Columns' payoffs and the oblique lines show the strategies for Row.

The solution (obtained algebraically) is 0.375 and thus Row 1 should be played with probability 0.375 and Row 2 with probability 0.625. Column will play strategy 1 with a probability that equals 0.75 and strategy 2 with probability that equals 0.25. Observe that the original game did not have a saddle; the approach requires assessing that the 2×2 game does not have either a saddle or dominance by a strategy, and then proceed as developed. The importance of this technique is that it allows for the solution of $n \times k$ zero-sum games by assessing mixed strategies in 2×2 subgames of the original $n \times k$ game (a result that is guaranteed by the minimax theorem (Straffin [3]), due to John von Neumann).

Figure 1 Graphical solution of two-person games: finding Row's probabilities

Beyond the 2×2 Game

A DM can use alternative criteria for choosing one course of action over another. We further discuss the *minimax*, *maximin*, and *expected value* using a situation in which Row now faces Nature in a 4×4 game (Straffin [3]):

	n_1	n_2	n_3	n_4
r_1	2	2	0	1
r_2	1	1	1	1
r_3	0	4	0	0
r_4	1	3	0	0

There is no row dominance. That is, no row has values that are at least as great in every column (and strictly greater in at least one column) as the values in all other rows. However, column 2 dominates all other columns. The minima of the rows are $[0, 1, 0, 0]$ with Row's maximin equal 1. The maxima of the columns are $[2, 4, 1, 1]'$ with Column's minimax equal 1 utility (' denotes transpose, i.e., writing a column as a row or *vice versa*). There are two saddle points at r_2, n_3 and at r_2, n_4 . If Row believes that all four columns are equally probable, then the strategy with the largest expected utility is r_1 , with $E(r_1) = 0.25 \times 2 + 0.25 \times 2 + 0.25 \times 0 + 0.25 \times 1 = 1.25$.

We can also calculate the *regrets* for Row, defined as the difference between the best payoff and the alternative payoffs, conditioned on each n_j , as shown

below:

	n_1	n_2	n_3	n_4
r_1	$2 - 2 = 0$	$4 - 2 = 2$	$1 - 0 = 1$	$1 - 1 = 0$
r_2	$2 - 1 = 1$	$4 - 1 = 3$	$1 - 1 = 0$	$1 - 1 = 0$
r_3	$2 - 0 = 2$	$4 - 4 = 0$	$1 - 0 = 1$	$1 - 0 = 1$
r_4	$2 - 1 = 1$	$4 - 3 = 1$	$1 - 0 = 1$	$1 - 0 = 1$

In this case, the row maxima are $[2, 3, 2, 1]'$ and, if we were to adopt the *minimax regret criterion*, then the optimal choice for Row by this criterion would be r_4 . If the expected regret was calculated using equal probabilities (pr) for the four states of nature ($\text{pr}(n_j) = 0.25$), then the result would be ambiguous (they would be r_2, r_3 , and r_4) because there are three equal and largest expected utility values.

Because different decision criteria lead to different optimal choices, several axioms have been developed to guide their selection. Some of those axioms are summarized in Table 2 and are related to the criteria for justifying that choice.

Searching for a Common Ground: Nash Equilibrium

The process of understanding rational decisions can be shown by the same normal form representation of strategies, $S_{i,j}$, consequences, $C_{i,j}$, and probabilities adopted in the previous section with the added understanding of the possibility of choices of strategies that are optimal. We use 2×2 games in which DMs can either cooperate or not. Some games do not allow sequential choices, while others do. Strategies, as course of actions, say cooperate, defect, attack, retreat, and so on, can be either pure (no probabilistic assessment is used: deterministic numbers are used) or mixed (probabilities play a role in assessing the eventual outcome from the situation confronting the DMs). A 2×2 game has two strategies per DM: for example, either defect or cooperate, but not both. We will discuss games that are effectuated simultaneously; further information is given in Burkett [5].

Pure Strategy Games

We begin with situations in which pure strategies are used to study what might happen. Consider, for example, the following situation in which DM1 and DM2 cannot cooperate – speak to one another (Table 3). The consequences (outcomes or payoffs)

Table 2 Selected axioms for decisional criteria^(a)

Axiom	Description	Criterion met by	Criterion not met by
Symmetry	Permuting rows or columns should not change the best choice	Maximin, expected value, regret	NR ^(b)
Dominance	When every row element is greater than another, the latter is inferior and can be ignored	Maximin, expected value, regret	NR
Linearity	Multiplying by a positive constant and/or adding a constant to all entries in the payoff matrix should not change the best choice	Maximin, expected value, regret	NR
Duplication of columns	Repeating columns should not change the best choice	Maximin, regret	Expected value
Addition of row	Repeating row or rows should not change the best choice	Maximin, expected value	Regret
Invariance to a change in utility	A constant amount of utility or disutility does not change the choice	Expected value, regret	Maximin
Comparability	Adding a weakly dominated row should not change the best choice of act	Expected value, regret	Maximin

^(a) Adapted from Straffin [3]^(b) Not reported**Table 3** Relationship between decision makers, actions and payoffs (large numbers are preferred to small numbers by both)

		Decision maker 1	
		S_1	S_2
Decision maker 2	S_1	4, 4	0, 6
	S_2	6, 0	3, 3

for two DMs are measured by numbers such that a number of large magnitude is preferred to one of smaller magnitude (for example, 3 is preferred to 2). If the numbers were to represent disbenefits, then the opposite interpretation is true. The first number in a cell is that for DM1 and the second is that for DM2:

What would these two DMs do in this situation? They would most likely select their dominant strategies. The dominant strategy for DM1 is $S_2 = 6$, 3 and the dominant strategy for DM2 is $S_2 = 6$, 3. DM1 and DM2 are aware of the consequences and, because they do not know what the other will do, will settle for the strategy that dominates as seen from the vantage point of the individual DM. Thus the solution will be 3, 3: neither of the two will be induced to deviate from his/her choice of dominant strategy. Clearly,

however, the optimal solution is 4, 4; if the two DMs could communicate, they would select S_1 as their solution to the game.

The solution identified by the couple 3, 3 is known as the *Nash equilibrium* for this game: it is the strategy that does not provide any incentive to move elsewhere from that solution. For the example, it is a unique Nash equilibrium. Some games have no Nash equilibrium while others can have multiple Nash equilibriums. Consider the game in Table 4:

This situation does not have a Nash equilibrium because the two DMs can switch strategy as there is no incentive to maintain a strategy regardless of what the other does.

Mixed Strategy Games

The distinguishing feature of mixed strategies is that each is characterized by probabilities. Continuing with the 2×2 representation, if strategy for DM1 has two outcomes, then one outcome has probability pr and the other has probability $(1 - pr)$. For the other DM, however, we label the probabilities as q and $(1 - q)$. Consider the earlier game as in Table 5.

We can calculate the expected payoffs as follows:

Table 4 Example of game without a Nash equilibrium

		Decision maker 1	
		S_1	S_2
Decision maker 2	S_1	Profits, does not profit	Does not profit, profits
	S_2	Does not profit, profits	Profits, does not profit

Table 5 Example for mixed strategy (also see Table 3) using arbitrary probabilities and leading to a unique Nash equilibrium

		Decision maker 1	
		S_1	S_2
Decision maker 2	S_1	4, 4	0, 6
	S_2	6, 0	3, 3

For DM2 and S_1 : $(pr)(4) + (1 - pr)(0) = (pr)(4)$.
 For DM2 and S_2 : $(pr)(6) + (1 - pr)(3) = (pr)(3) + 3$.

For DM1 and S_1 : $(q)(4) + (1 - q)(0) = (pr)(4)$.
 For DM2 and S_2 : $(q)(6) + (1 - q)(3) = (q)(3) + 3$.

Putting arbitrary probabilities (0.5) in these expressions, we obtain:

For DM2 and S_1 : $(0.5)(4) + (1 - 0.5)(0) = (pr)(4)$. For DM2 and S_2 : $(0.5)(6) + (1 - 0.5)(3) = (0.5)(3) + 3 = 4.5$.

For DM1 and S_1 : $(0.5)(4) + (1 - 0.5)(0) = (0.5)(4)$. For DM2 and S_2 : $(0.5)(6) + (1 - 0.5)(3) = (0.5)(3) + 3 = 4.5$.

It follows that the game characterized by the unique Nash equilibrium remains unchanged. This is not the case for the other example that did not have a Nash equilibrium (Table 6).

The mixed strategies approach changes the deterministic results. Putting arbitrary probabilities (0.5) in these expressions, we obtain

For DM2 and S_1 : $(0.5)(1) + (1 - 0.5)(0) = 0.5$.
 For DM2 and S_2 : $(0.5)(1) + (1 - 0.5)(0) = 0.5$.
 For DM1 and S_1 : $(0.5)(0) + (1 - 0.5)(1) = 0.5$.
 For DM2 and S_2 : $(0.5)(0) + (1 - 0.5)(1) = (0.5)(3) + 3 = 0.5$.

The result is Nash equilibrium for these probabilities: both DMs are indifferent to the strategy of the other.

The concepts of sequential games [5], where the choices made by the DMs account for the evolution of the choices, can be illustrated (Figure 2) as a decision tree in which the lines are the *branches* of the tree:

Each branch identifies a possible strategy that can be taken by a DM. This tree identifies simple binary choices and payoffs, which can be positive (+), negative (−), or zero (0). Reading the tree from left to right leads to an understanding of how the two DMs can behave and their possible final choices. DM1 would probably *do*, while DM2 might try to change the game, if it were possible.

**Figure 2** Simple example of sequential decision making involving two decision makers and two binary choices**Table 6** Example for mixed strategies showing indifference to each other's choice

		Decision maker 1	
		S_1	S_2
Decision maker 2	S_1	Profits = 1, does not profit = 0	Does not profit = 0, profits = 1
	S_2	Does not profit = 0, profits = 1	Profits = 1, does not profit = 0

Discussion

The relevance of studying situations of conflict through these methods is suggested by the following considerations:

- The structure of a game is unambiguously described.
- The payoffs, either inutilities or other suitable units, are quantitative expressions of each stakeholder's attitude.
- The methods for solving these games are theoretically sound and replicable.
- The criteria for choosing an alternative strategy over another consider both stakeholders.
- The resolution of some of the ambiguities inherent to such games may exist and be unique to that game.
- The difference between individual and societal choices can be shown in a coherent framework.

In the end, it is preferable to have more information than less (not necessarily, e.g., mutual insurance can be destroyed by free information, reducing everyone's expected utility); thus, anticipating the outcomes of a dispute provides useful information by orienting and informing a choice.

How does this theoretical framework compare with actual behavior? The basis for game theory is that DMs optimize their choices and seek more utility, rather than less. Although this basis is theoretically sound, there have been many cases of violations in simple, practical situations. Some, for example, Kahneman and Tversky (1979) found that actual behavior affects decision making to the point that the theory, while sound, required modifications, thus resulting in prospect theory. Camerer and Fehr [6] have also found that DMs inherently act altruistically and thus are not money maximizers.

Glimcker [7] reports the following. He uses the game *work* or *shirk* in a controlled setting: the employer faces the daily decision of going to work; the employer has the choice to inspect the employee's performance. For example consider Glimcker [7, p. 303, Table 12.2] (with change in terminology). The two stakeholders incur daily monetary costs and benefits in unstated monetary units, as shown in Table 7.

In general, because inspection cost is high, the employer will be allowed some shirking. If the inspection cost was lower, they could result in

Table 7 Wage–leisure trade-offs with or without cost of controlling the employees' attendance

	Employer checks attendance	Employer does not check
Employee works	Wage – leisure, revenue – wage – inspection cost (100 – 50 = 50, 125 – 100 – 50 = 25)	Wage – leisure, revenue – wage (50, 25)
Employee shirks	0, –inspection cost (0, –50)	Wage, –wage (100, –100)

more inspection and thus lead to decreasing rates of shirking: the result is Nash's equilibrium. For the employer, the hazard rates are (*shirk*) = ($\$inspec$ tion/ $\$wage$); (*inspect*) = ($\$leisure/\$wage$). The Nash equilibrium is (the result is obtained by solving for the probabilities, e.g., $50 \times x + (1 - x) \times 50 = 100 - 100 \times x$; thus $x = 0.5$) shirk 50% of the time and inspect 50% of the time [7, p. 304]. Students (unfamiliar with game theory) were enrolled in the shirk–inspect game to assess if their behavior was consistent with this theoretical equilibrium. In the first 100 (out of approximately 140) tests, the stakeholders modified their outcomes and *tended* toward the Nash equilibrium. When the payoffs were changed, the results changed as well.

The *shirk-work* game discussed in Glimcker [7] provides some interesting insights on the sequential choices made between either working or shirking, when deciding which alternative to take by the worker who is initially contemplating the choice of either working or shirking work. The results show that the worker (in an experiment involving 150 trials) appears to be acting randomly and thus keeps the employer guessing as to what course of action she will actually take. This author reports (adapted from Figure 12.2, p. 308) that the choices, made in 150 games, has the results as in Figure 3.

The decision tree shows the chronology of the decision. The initial choices are to either work or shirk. The second decision, conditioned (the conditionalization is symbolized by the symbol “[|]”), is to *work* | *work*, *shirk* | *work*, and so on, as depicted by the tree. It appears that the worker is acting randomly and thus keeps the employer guessing!

Clearly, individual choices cannot be divorced from the fact that those choices are made in the

Figure 3 Decision tree depicting the alternatives in the wage-shirking work game

brain. Interestingly, it is now increasingly apparent that humans have [8] ... *at least two systems working when making moral judgments* ... *There is an emotional system that depends on (the ventromedial prefrontal cortex) ... and another that performs more utilitarian cost-benefit analyses which in these people is intact.* When that region is damaged, individuals opt for choices that are different from those not damaged. For example, in a relatively small sample of respondents, only approximately 20% of *normal* individuals answered *yes*, while approximately 80% of individuals with damaged brain answered *yes*, to the following question:

You have abandoned a sinking cruise ship and are in a crowded lifeboat that is dangerously low in the water. If nothing is done it will sink before the rescue boats arrive and everyone will die. However, there is an injured person who will not survive in any case. If you throw the person overboard, the boat will stay afloat and the remaining passengers will be saved. Would you throw this person overboard in order to save the lives of the remaining passengers?

Now consider a different choice (Carey [8]): having to divert a train by *flipping a switch*, to save five workers, knowing that such diversion would kill one other worker for sure. The research shows that those with the brain injury, normal individual, and those with a different type of brain injury would divert the train. When that certainty of killing the

single worker was not apparent, all of the three groups rejected the trade-off. Moreover, if the action did not comport flipping a switch but, rather, the act was equivalent to pushing that single individual to certain death to save several others at risk, the results by all of the three groups were still different: those with the ventromedial injury were *about twice as likely as other participants to say that they would push someone in front of the train (if that were the only option ...)*. Although the brain injury is uncommon, the responses may make some think twice about the implications of either answer.

Confounding

In the presence of confounding, the old adage “association is not causation” holds even if the study population is arbitrarily large. For example, consider a very large cohort study (*see Cohort Studies*) whose goal is estimating the causal effect of receiving the treatment (the exposure) A on the risk of death (the outcome) Y . Investigators compute the risk ratio $\Pr[Y = 1|A = 1] / \Pr[Y = 1|A = 0]$, where A is 1 if the subject received the exposure and 0 otherwise, as a measure of the association between A and Y . However, what investigators would really want to compute is the causal risk ratio $\Pr[Y_{a=1} = 1] / \Pr[Y_{a=0} = 1]$, where, for each subject, Y_a is the (possibly counterfactual) outcome that would have been observed had the subject received exposure level a . We say that there is confounding if, for example, subjects with the worst prognosis received treatment $A = 1$. When there is confounding, the value of the associational risk ratio may be very different from that of the causal risk ratio, even in the absence of other sources of bias. For simplicity of presentation, let us assume throughout this chapter that other sources of bias (e.g., selection bias, measurement error, and sampling variability) are absent. This chapter is organized as follows.

First, we use causal graphs (*see Causal Diagrams*) to describe the causal structure that gives rise to confounding. Causal directed acyclic graphs (DAGs) [1–3] have been increasingly used in epidemiology [4–6] and other disciplines. Nodes in DAGs represent variables, both measured and unmeasured, that are linked by arrows. A causal DAG is one in which the arrows can be interpreted as direct causal effects, and all common causes of any pair of variables are included in the graph. Causal DAGs are acyclic because a variable cannot cause itself, either directly or through other variables. A path in a DAG is any arrow-based route between two variables in the graph. A path is causal if it follows the direction of the arrows, and noncausal otherwise. As an example, the causal DAG in Figure 1 represents the dichotomous variables A (ever smoker) and Y (lung cancer)

Figure 1 A simple causal DAG

linked by a single causal path. The lack of other variables in the DAG indicates that no common causes of A and Y are believed to exist. A major strength of using DAGs is that a set of simple graphical rules can be applied to determine whether two variables are unassociated under the causal assumptions encoded in the graph. These rules, known as *d-separation rules*, are summarized in the Appendix.

Second, we review a condition under which confounding can be eliminated. This condition will be referred to as a condition for the identifiability of causal effects. Third, we examine the definition of confounder that logically follows from the identifiability condition. Fourth, we describe an alternative, counterfactual-based definition of confounding that is mathematically equivalent to the structural (graphical) definition of confounding. Finally, we provide a classification of the methods to eliminate the measured confounding using data on the available confounders. Let us now turn our attention to the causal structure that underlies confounding bias.

The Structure of Confounding

Confounding is the bias that arises when the exposure and the outcome share a common cause. The structure of confounding can be represented by using causal DAGs. For example, the causal DAG in Figure 2(a) depicts an exposure A , an outcome Y , and their common cause L . This DAG shows two sources of association between exposure and outcome: (i) the path $A \rightarrow Y$ that represents the causal effect of A on Y and (ii) the path $A \leftarrow L \rightarrow Y$ between A and Y that is mediated by the common cause L . In graph theory, a path like $A \leftarrow L \rightarrow Y$ that links A and Y through their common cause L is referred to as a *backdoor path*. More generally, in a causal DAG, a backdoor path is a noncausal path between exposure and outcome that does not include any variable causally affected by (or, in graph-theoretic terms, any descendant of) the exposure.

If the common cause L did not exist in Figure 2(a), then the only path between exposure and outcome would be $A \rightarrow Y$, and thus the entire association between A and Y would be due to the causal effect of A on Y . That is, association would be causation; the associational risk ratio $\Pr[Y = 1|A = 1] / \Pr[Y = 1|A = 0]$ would equal the causal risk ratio $\Pr[Y_{a=1} = 1] / \Pr[Y_{a=0} = 1]$.

Figure 2 Examples of traditional “confounders”

But the presence of the common cause L creates an additional source of association between the exposure A and the outcome Y , which we refer to as confounding for the effect of A on Y . Because of confounding, association is not causation; the associational risk ratio does not equal the causal risk ratio.

Examples of confounding abound in observational research. Consider the following examples of confounding for various kinds of exposures in relation to health outcomes:

Occupational factors

- The effect of working as a firefighter A on the risk of death Y will be confounded if “being physically fit” L is a cause of both being an active firefighter and having a lower mortality risk. This bias, depicted in the causal DAG in Figure 2(a), is often referred to as a *healthy worker bias*.

Drug use and other clinical decisions

- The effect of use of drug A (say, aspirin) on the risk of disease Y (say, stroke) will be confounded if the drug is more likely to be prescribed to individuals with certain condition L (say, heart disease) that is both an indication for treatment and a risk factor for the disease. Heart disease L may be a risk factor for stroke Y because L has a direct causal effect on Y as in Figure 2(a) or, as represented in Figure 2(b), because both A and Y are caused by atherosclerosis U , an unmeasured variable. This bias is known as *confounding by indication* or *channeling*, the last term often being reserved to describe the bias created by patient-specific risk factors L that encourage doctors to use certain drug A within a class of drugs.

Lifestyle

- The effect of behavior A (say, heavy alcohol intake) on the risk of Y (say, death) will be confounded if the behavior is associated with another behavior L (say, cigarette smoking) that has a causal effect on Y and tends to co-occur with A . The structure of the variables L , A , and Y is depicted in the causal DAG in Figure 2(c), in which the unmeasured variable U represents the sort of personality that leads to both heavy drinking and smoking.

Genetic factors

- The effect of a DNA sequence A on the risk of developing certain trait Y will be confounded if there exists a DNA sequence L that has a causal effect on Y and is more common among people carrying A . This bias, also represented by the causal DAG in Figure 2(c), is known as *linkage disequilibrium* or *population stratification*, the last term often being reserved to describe the bias arising from conducting studies in a mixture of individuals from different ethnic groups. Thus the variable U can stand for ethnicity or other factors that result in linkage of DNA sequences.

Social factors

- The effect of income at age 65, A , on the level of disability at age 75 Y will be confounded if the level of disability at age 55 L affects both future income and disability level. This bias may be depicted by the causal DAG in Figure 2(a).

Environmental exposures

- The effect of airborne particulate matter A on the risk of coronary heart disease Y will be confounded if other pollutants L whose levels covary with those of A cause coronary heart disease. This bias is also represented by the causal DAG in Figure 2(c), in which the unmeasured variable U represent weather conditions that affect the levels of all types of air pollution.

In all these cases, the bias has the same structure: it is due to the presence of a common cause (L or U) of the exposure A and the outcome Y , or, equivalently, to the presence of an unblocked backdoor path between A and Y . We refer to the bias caused by common causes as confounding. We use other names

to refer to biases caused by structural reasons other than the presence of common causes. For example, we say that selection bias is the result of conditioning on common effects [7].

Confounding and Identifiability of Causal Effects

Once confounding is structurally defined as the bias resulting from the presence of common causes of exposure and outcome, the key question is, under what conditions can confounding be eliminated? In other words, in the absence of measurement error and selection bias, under what conditions can the causal effect of exposure A on outcome Y be (nonparametrically) identified? An important result from graph theory, known as *the backdoor criterion* [1], is that the causal effect of exposure A on the outcome Y is identifiable if all backdoor paths between them can be blocked. Thus the two settings in which causal effects are identifiable are as follows:

1. *No common causes*
If, as in the causal DAG of Figure 1, there are no common causes of exposure and outcome, and hence no backdoor paths that need to be blocked, we say that there is no confounding.
2. *Common causes but enough measured variables to block all backdoor paths*
If, as in the causal DAG of Figure 2(a), the backdoor path through the common cause L can be blocked by conditioning on the measured covariates (in this example, L itself), we say that there is confounding but no unmeasured confounding.

The first setting is expected in simple randomized experiments in which all subjects have the same probability of receiving exposure. In these experiments, confounding is not expected to occur because exposure is determined by the flip of a coin – or its computerized upgrade, the random number generator – and the flip of the coin cannot be a cause of the outcome.

The second setting is expected in randomized experiments in which the probability of receiving exposure is the same for all subjects with the same value of risk factor L but, by design, this probability varies across values of L . The design of these experiments guarantees the presence of confounding,

because L is a common cause of exposure and outcome, but in these experiments confounding is not expected conditional on – within levels of – the covariates L . This second setting is also what one hopes for in observational studies in which many variables L have been measured.

The backdoor criterion answers three questions: (i) does confounding exist? (ii) can confounding be eliminated? and (iii) what variables are necessary to eliminate the confounding? The answer to the first question is affirmative if there exist unblocked backdoor paths between exposure and outcome; the answer to the second question is affirmative if all those backdoor paths can be blocked by conditioning on the measured variables; the answer to the third question is the minimal set of variables that, when conditioned on, block all backdoor paths. The backdoor criterion, however, does not answer questions regarding the magnitude of the confounding. It is logically possible that some unblocked backdoor paths are weak (e.g., if L does not have a large effect on either A or Y) and thus induce little bias, or that several strong backdoor paths induce bias in opposite directions and thus result in a weak net bias.

Note that, even though the application of the backdoor criterion requires conditioning on the variables L , the backdoor criterion does not imply that conditioning or restriction is the only possible method to eliminate confounding. Conditioning is only a graphical device to determine whether a certain variable in L can be used to block the backdoor path. The section titled “Methods to Adjust for Confounding” provides an overview of the methods that eliminate confounding using data on the confounders. First let us review the definition of confounder.

Confounding and Confounders

Confounding is the bias that results from the presence of common causes of exposure and outcome. A *confounder* is any variable that can be used to reduce such bias, that is, any variable that can be used to block a backdoor path between exposure and outcome. In contrast with this structural definition, confounder was traditionally defined as any variable that meets the following three conditions: (i) it is associated with the exposure, (ii) it is associated with the outcome conditional on exposure (with “conditional on exposure” often replaced by “in the

unexposed”), and (iii) it does not lie on a causal pathway between exposure and outcome. According to this traditional definition, all confounders so defined should be adjusted for in the analysis. However, this traditional definition of confounder may lead to inappropriate adjustment for confounding [2, 4]. To see why, let us compare the structural and traditional definitions of confounder in Figure 2(a–d).

In Figure 2(a) there is confounding because the exposure A and the outcome Y share the common cause L , i.e., because there is a backdoor path between A and Y through L . However, this backdoor path can be blocked by conditioning on L . Thus, if the investigators collected data on L for all individuals, there is no unmeasured confounding given L . We say that L is a confounder because it is needed to eliminate confounding. Let us now turn to the traditional definition of confounder. The variable L is associated with the exposure (because it has a causal effect on A), it is associated with the outcome conditional on the exposure (because it has a direct effect on Y), and it does not lie on the causal pathway between exposure and outcome. Then, according to the traditional definition, L is a confounder and it should be adjusted for. There is no discrepancy between the structural and traditional definitions of confounder for the causal DAG in Figure 2(a).

In Figure 2(b) there is confounding because the exposure A and the outcome Y share the common cause U , i.e., there is a backdoor path between A and Y through U . (Unlike the variables L , A , and Y , we suppose that the variable U was not measured by the investigators.) This backdoor path could be theoretically blocked, and thus confounding eliminated, by conditioning on U , had data on this variable been collected. However, this backdoor path can also be blocked by conditioning on L . Thus, there is no unmeasured confounding given L . We say that L is a confounder because it is needed to eliminate confounding, even though the confounding resulted from the presence of U . Let us now turn to the traditional definition of confounder. The variable L is associated with the exposure (because it has a causal effect on A), it is associated with the outcome conditional on the exposure (because it shares the common cause U with Y), and it does not lie on the causal pathway between exposure and outcome. Then, according to the traditional definition, L is a confounder and it should be adjusted for. Again, there is no discrepancy between the structural and

traditional definitions of confounder for the causal DAG in Figure 2(b).

In Figure 2(c) also there is confounding because the exposure A and the outcome Y share the common cause U , and the backdoor path can also be blocked by conditioning on L . Therefore, there is no unmeasured confounding given L , and we say that L is a confounder. Because L is associated with the exposure (it shares the common cause U with A), it is associated with the outcome conditional on the exposure (it has a causal effect on Y), and it does not lie on the causal pathway between exposure and outcome, then, according to the traditional definition, L is a confounder and it should be adjusted for. Again, there is no discrepancy between the structural and traditional definitions of confounder for the causal DAG in Figure 2(c).

The key figure is Figure 2(d). In this causal DAG there are no common causes of exposure A and outcome Y , and therefore no confounding. In graph-theoretical terms, the backdoor between A and Y through L ($A \leftarrow U_2 \rightarrow L \leftarrow U_1 \rightarrow Y$) is blocked because L is a collider on that path (see Appendix). Association is causation. There is no need to adjust for L in any way. In fact, conventional adjustment for L would introduce (selection) bias because conditioning on L would open the otherwise blocked backdoor path between A and Y . However, L is associated with the exposure (it shares the common cause U_2 with A), it is associated with the outcome conditional on the exposure (it shares the common cause U_1 with Y), and it does not lie on the causal pathway between exposure and outcome. Hence, according to the traditional definition, L is a confounder and it should be adjusted for. In this example, the traditional definition labels L as a confounder even in the absence of confounding bias. The result of trying to adjust for this nonexistent confounding is selection bias. This particular example of selection bias has been referred to as *M-bias* [8] because the structure of the variables involved in it – U_2, L, U_1 – resembles a letter M (lying on its side in Figure 2d). Some authors (e.g., Greenland, Poole, personal communication) refer to this type of M-bias, or to any bias that results from selection on preexposure factors, as confounding rather than as selection bias. This choice of terminology slightly extends the meaning of the term “confounding” to some situations in which no common causes exist, but this extension has no practical consequences:

adjusting for L in Figure 2(d) creates bias, regardless of its name.

We have described an example in which the standard definition of confounder fails because it misleads investigators into adjusting for a variable when adjustment for such a variable is not only superfluous but also harmful. This problem arises because the standard definition treats the concept of confounder, rather than that of confounding, as the primary concept. In contrast, the structural definition first characterizes confounding as the bias resulting from the presence of common causes and then characterizes confounder as any variable that is necessary to eliminate the bias in the analysis. For all practical purposes, confounding is an absolute concept – common causes of exposure and the outcome either exist or do not exist in our region of the universe – whereas confounder is a relative concept – a variable L may be needed to block a backdoor path only when another variable U is not measured. A related problem is that the standard definition defines confounder in terms of statistical associations (a variable associated with the exposure, etc.) that may exist even when confounding (due to common causes) does not exist as shown in Figure 2(d). Confounding is a causal concept that cannot be reduced to statistical terms.

Consider now the causal DAG in Figure 3. In this graph there is confounding for the effect of A on Y because of the presence of the unmeasured common cause U . The measured variable L is a proxy or surrogate for the common cause U . For example, the unmeasured variable socioeconomic status U may confound the effect of physical activity A on the risk of cardiovascular disease Y . Income L is a surrogate for the often ill-defined variable socioeconomic status. Should we consider the variable L as a confounder? On the one hand, L cannot be used to block the backdoor path between A and Y because it does not lie on that path. On the other hand, adjusting for L would indirectly adjust for some of the confounding caused by U because L is correlated with U . In the extreme, if L were perfectly correlated with U ,

Figure 3 A surrogate confounder

then it would make no difference whether we one conditions on L or on U . That is, conditioning on L results in a partial blockage of the backdoor path $A \leftarrow U \rightarrow Y$, and we will usually prefer to adjust, rather than not to adjust, for L . We refer to variables like L as *surrogate confounders*.

For pedagogic purposes, all causal DAGs represented in this chapter include non-time-varying exposures only. However, the above definitions of confounding and confounders can be generalized to the case of time-varying exposures. Pearl and Robins [9] described the generalized backdoor criterion for the identifiability of the effects of time-varying and generalized exposures. A time-varying confounder is any time-varying variable that is needed to identify the effect of a time-varying exposure. Settings with time-varying confounders and exposures make it even clearer why the traditional definition of confounding, and the conventional methods for confounding adjustment, may result in selection bias. See [7] for an informal introduction to the problems associated with time-varying exposures and confounders, and [10] for a more formal treatment.

Confounding and Exchangeability

So far, we have defined confounding from a structural standpoint: the bias induced by common causes of exposure and outcome. However, it is also possible to provide a precise definition of confounding based on the implications of its structure, with no explicit reference to common causes.

Take our second example of confounding above: the individuals exposed to aspirin are different from the unexposed because, if the exposed had remained unexposed, their risk of stroke would have been higher than that of those that did actually remain unexposed – because the exposed had a higher frequency of heart disease, a common cause. Thus the consequence of the existence of common causes of exposure and outcome is that the exposed and the unexposed are not “comparable” or, more technically, that they are not exchangeable [11]. Exchangeability can be represented mathematically by using counterfactuals (see, for example [12]). For a dichotomous exposure A and outcome Y , exchangeability means that the equality $\Pr[Y_a = 1] = \Pr[Y = 1|A = a]$ holds for all a .

Confounding can then be defined as the bias that results from the presence of common causes of exposure and outcome (a structural definition) or as the bias that results from lack of exchangeability of the exposed and the unexposed (a counterfactual-based definition). In the absence of bias caused by selection or mismeasurement, both definitions are mathematically equivalent. When the exposure is randomly assigned, the exposed and the unexposed are expected to be *exchangeable* because no common causes exist (no confounding). When the exposure is not randomly assigned, investigators measure many variables in an attempt to ensure that the exposed and the unexposed are *conditionally exchangeable* given the measured covariates L because, even though common causes may exist (confounding), investigators assume that the variables L are sufficient to block all backdoor paths (no unmeasured confounding).

However, an exchangeability-based definition of confounding that does not explicitly specify the common cause(s) responsible for the bias has limited practical utility in observational research. This is so because methods to adjust for confounding in observational studies require adjustment for variables (i.e., L in Figure 2a–c) other than exposure A and outcome Y , and therefore detailed knowledge about the structure of the bias is needed to decide on which variables to measure. In the next section, we review the methods that can be used to eliminate confounding when enough confounders L are available to block all backdoor paths between exposure and outcome.

Methods to Adjust for Confounding

Randomization is the preferred method to control for confounding because a random assignment of exposure is expected to produce exchangeability of the exposed and the unexposed (*see Randomized Controlled Trials*). When the exposure is randomly assigned in large samples, investigators need not wonder about common causes of exposure and outcome because randomization precludes their existence. As a consequence, subject-matter knowledge to identify appropriate adjustment variables is unnecessary. In contrast, all other methods to eliminate confounding require expert knowledge – because the judgment as to which variables on a DAG cause which others must in general be based on subject

matter considerations – and succeed only under the uncheckable assumption that this knowledge is sufficient to identify and block all backdoor paths between exposure and outcome.

The goal of all methods to eliminate measured confounding is estimation of the effect of an exposure A on an outcome Y in a certain population. These methods can be classified into the two following categories:

1. Methods that estimate the causal effect in one or more subsets of the population in which no measured confounding exists.

These methods – including restriction, stratification, and matching – compare the distribution of the outcome between exposed and unexposed in such subset(s) of the population.

(a) Restriction

Limiting the analysis to one stratum of the covariates in L , a method known as *restriction*, estimates the effect of the exposure on the outcome in the selected stratum, which may differ from the effect in the population if effect measure modification exists. The investigators may restrict their analysis of aspirin A and stroke Y to the subset of subjects without a history of heart disease ($L = 0$). By conditioning on $L = 0$, an action that can be graphically represented as a box around variable L in Figure 2(a), the backdoor path from A to Y is blocked and thus the association, if any, between exposure A and outcome Y can be entirely attributed to the causal effect of A on Y (under the assumption of no unmeasured confounding given L). In other words, the exposed and the unexposed are exchangeable in the stratum $L = 0$ or, equivalently, the distribution of the outcome Y in the exposed (unexposed) in the stratum $L = 0$ equals the distribution of the counterfactual outcome if all subjects in the stratum $L = 0$ had been exposed (unexposed).

(b) Stratification

In the above example, a stratified analysis is simply an analysis conducted separately in each of the two strata of history of heart disease L (0: no, 1: yes). Thus stratification is simply the application of restriction to several comprehensive and mutually exclusive

subsets of the population. The conditioning on each value of L , which can be represented as a box around variable L in Figure 2(a), results in two association measures between A and Y , one per stratum of L , that can be interpreted as the causal effect of A on Y in each stratum (under the assumption of no unmeasured confounding given L). Often, when effect measure modification is not believed to exist, the stratum-specific effect measures are pooled to increase the statistical efficiency of the estimation. Conventional parametric or semiparametric regression models are a sophisticated version of stratification in which conditional effect measures are estimated within levels of all the covariates in the model. Not including interaction terms between exposure and covariates in the regression model is equivalent to assuming that all conditional effect measures (i.e., stratum-specific for discrete variables) are equal.

(c) Matching

Another method for the elimination of measured confounding is that of selecting the exposed and the unexposed so that both groups have the same distribution of the variables in L . For example, in our aspirin and stroke example, one could find one (or more) unexposed subject with $L = 0$ for each exposed subject with $L = 0$. In the resulting matched population, a subset of the entire population, a history of heart disease L does not predict whether the patients are exposed to aspirin A and thus there is no measured confounding by L . This method estimates the effect of A on Y in a subset of the population with the same distribution of L as the exposed so that, under the assumption of no unmeasured confounding given L , this method estimates the effect in the exposed.

A common variation of restriction, stratification, and matching replaces the variable L by the probability of receiving exposure $\Pr[A = 1|L]$, usually referred to as the *propensity score*. When L is high dimensional (say, a vector of 20 covariates), propensity score-based methods can be seen as a dimension reduction strategy that allows investigators to work with one scalar variable, the propensity score, which

is in itself sufficient to block the same backdoor paths that can be blocked by the multiple variables in L [13].

2. Methods that estimate the causal effect in the entire population or in any subset of it.

These methods – including standardization, inverse probability weighting, and g-estimation – simulate the distribution of the (counterfactual) outcomes in the population if no measured confounding had existed. A detailed description of these methods is beyond the scope of this chapter, but they all use the assumption that there is no unmeasured confounding within strata of the variables in L (i.e., that all backdoor paths can be blocked) to simulate the association between A and Y in the population if there had actually been no measured confounding (no backdoor paths mediated through L). Hence, under the assumption of no unmeasured confounding given L , the simulated association between A and Y can be entirely attributed to the effect of A on Y . For example, in the analysis of aspirin A and stroke Y , these methods would simulate the distribution of the outcomes if the probability of receiving aspirin had been the same regardless of a subject's heart disease history L . This can be represented in Figure 2(a) by deleting the arrow from L to A . In other words, the exposed and the unexposed are exchangeable in the simulated population or, equivalently, the distribution of the outcome Y in the exposed (unexposed) equals the distribution of the counterfactual outcome if all subjects in the population had been exposed (unexposed). These methods can also be applied to a subset of the population, if so desired. The parametric and semiparametric extensions of these methods are the parametric g-formula for standardization [14], marginal structural models for inverse probability weighting [15], and nested structural models for g-estimation [16]. Unlike the methods based on restriction, stratification, or matching, these methods can appropriately adjust for measured time-dependent confounding [10].

All the methods listed above require the assumption of no unmeasured confounding given L for the effect of exposure A on outcome Y , that is, the assumption that investigators have measured enough variables L to block all backdoor paths from A to Y . (Technically, g-estimation requires the slightly

weaker assumption that the amount of unmeasured confounding given L is known, of which the assumption of no unmeasured confounding is a particular case.) Other methods not listed above – instrumental variable methods – use a different set of assumptions to estimate the causal effect of A on Y in observational studies. Among other things, these methods require the measurement of a variable I , the instrument, such that there is no unmeasured confounding for the effect of I on Y and that the effect of I on Y is entirely mediated through A . For a review of the assumptions underlying instrumental variable methods, see [17]. The assumptions required by instrumental variable methods may be stronger than the assumption of no unmeasured confounding for the effect of A on Y . However, because all these assumptions are not empirically verifiable, it will be often unclear which set of assumptions is more likely to hold in a particular setting.

Note that the existence of common causes of exposure and outcome, and thus the definition of confounding, does not depend on the method used to adjust for it or on the results obtained from these methods. Hence we do not say that measured confounding exists simply because the adjusted estimate is different from the unadjusted estimate. In fact, one would expect that the presence of measured confounding lead to a change in the estimate, but not necessarily the other way around. Changes in estimates may occur for reasons other than confounding, including the introduction of selection bias when adjusting for nonconfounders [18] and the use of noncollapsible effect measures like the odds ratio (see **Odds and Odds Ratio**) in a closed cohort study (see **Cohort Studies**) [19]. Attempts to define confounding based on change in estimates have been long abandoned because of these problems.

Conclusion

The structural definition of confounding emphasizes that causal inference from observational data requires *a priori* causal assumptions or beliefs, which must be derived from subject-matter knowledge, and not only from statistical associations detected in the data. As shown in Figure 2(d), statistical criteria are insufficient to characterize confounding and can lead to inconsistencies between beliefs and actions in data analysis.

Knowledge of the causal structure is a prerequisite to determine the existence of confounding and to accurately label a variable as a confounder. In practice, however, this requirement may impose such an unrealistically high standard on the investigator that many studies simply cannot be done at all. A more realistic recommendation for researchers is to avoid adjusting for a variable L unless they believe it may possibly be a confounder, i.e., it may block a backdoor path. At the very least, investigators should generally avoid stratifying on variables affected by either the exposure or the outcome. Of course, thoughtful and knowledgeable investigators could believe that two or more causal structures, possibly leading to different conclusions regarding confounding and confounders, are equally plausible. In that case they would perform multiple analyses and explicitly state the assumptions about causal structure required for the validity of each. Unfortunately, one can never be certain that the set of causal structures under consideration includes the true one; this uncertainty is unavoidable with observational data.

Appendix: d-Separation

In a DAG, each path is blocked according to the following graphical rules [1]:

1. If there are no variables being conditioned on, a path is blocked if and only if two arrowheads on the path collide at some variable (known as a *collider*) on the path.
2. Any path that contains a noncollider that has been conditioned on is blocked. We use a square box around a variable to indicate that we are conditioning on it.
3. A collider that has been conditioned on does not block a path.
4. A collider that has a descendant that has been conditioned on does not block a path.

Rules 1–4 can be summarized as follows. A path is blocked if and only if it contains a noncollider that has been conditioned on, or it contains a collider that has not been conditioned on and has no descendants that have been conditioned on. Two variables are d-separated if all paths between them are blocked (otherwise they are d-connected). Some conclusions that follow from the method of d-separation are that causes (ancestors) are not independent of their effects

(descendants) and *vice versa*, and that generally two variables are associated if they share a common cause. Another important conclusion is that sharing a common effect does not imply that two causes are associated. Intuitively, whether two variables (the common causes) are correlated cannot be influenced by an event in the future (their effect), but two causes of a given effect generally become associated once we stratify on the common effect.

Finally, two variables that are not d-separated may actually be statistically independent. The reason is that it is logically possible that causal effects in opposite directions may exactly cancel out. Because exact cancellation of causal effects is probably a very rare event in natural circumstances, d-separation and independence may be treated in practice as equivalent concepts with little risk. In the probably rare occasions in which two variables are simultaneously d-connected and statistically independent, we say that the joint distribution of the variables in the DAG is not faithful to the DAG [3].

Considerations in Planning for Successful Risk Communication

As has been previously discussed, risk communication is an integral and vital component of risk assessment and risk management (*see* **Role of Risk Communication in a Comprehensive Risk Management Approach**). However, successful risk communication does not “just happen” – it is the result of careful planning and consideration of multiple needs and objectives.

Much guidance has been provided on conducting risk communication. This has involved several different approaches over the last 20 years, including: (a) the “Message Transmission Model for Risk Communication” [1]; (b) the Communication Process Model [2]; (c) the “Improving Risk Communication” approach of the US National Research Council [3]; (d) the Seven Cardinal Rules of Risk Communication [4, 5]; (e) the “Hazard *versus* Outrage” approach [6]; (f) the “Mental Models” approach [7–9]; (g) the “Analytic–Deliberative Process” approach [10]; and (h) the considerations outlined by the US Presidential/Congressional Commission on Risk Assessment and Risk Management [11]. All of these approaches have provided insights into the risk communication process and advice on improving the effectiveness of risk dialogues.

However, it is important to recognize there is no “magic” set of rules that, if followed, will always ensure effective risk communication and accepted risk-management decisions. Nonetheless, there are certain considerations that can provide guidance in planning and executing risk communication efforts to enhance opportunities for productive dialogues.

Successful Risk Communication Considerations

There is no “cookbook” formula for risk communication

This is the first and foremost consideration in good risk communication. Risk communication efforts must be based on the specific circumstances surrounding each risk situation. A rigid or “one size fits

all” protocol for public participation and communication cannot possibly accommodate the diverse circumstances of all cases [12]. Attempts to reduce risk communication to a rote procedure will inevitably result in a less than optimal process and ineffective (if not outright damaging) results.

Planning is required for any effort to be effective

Notwithstanding the above, risk communication requires a certain degree of planning to be effective. A risk communication plan will help focus efforts, ensure that nothing is overlooked and keep everyone informed. Risk communication frameworks usually proceed in a linear, but iterative, fashion starting with problem formulation and proceeding through to communications strategy design and implementation. Evaluation plays a very important role in the framework, and should be conducted at the beginning, during, and at the end of the program (*see* **Evaluation of Risk Communication Efforts**). Any risk communication plan must be considered a “living” document that grows and evolves throughout a risk assessment program [3, 10, 11].

All interested and affected parties should be given the opportunity to be involved at the outset of, and throughout, the risk process

Stakeholder involvement is a critical component in risk communication. Involving the appropriate people from the beginning of the process, when the problem is being formulated, helps to ensure that the right problem is being addressed in the right way [10, 11].

Achieving and maintaining mutual trust and credibility are critical to communication success

As noted by Slovic [13, 14], trust is not automatic, nor everlasting – it is difficult to gain, even harder to maintain, and once lost, almost impossible to regain. Incorporation of a fair, open process of public participation and dialogue has been advocated as one important means of increasing public trust [12, 15].

Communication must be seen as a process, and not simply as effects

Risk communication is not simply relaying a one-way message about risk to those potentially affected by the risk situation. It is instead a process of mutual learning, discourse, and negotiation on both the nature of the risk and the best means of managing the risk in a manner acceptable to all involved [3].

All communication should be open, honest, and accurate

Many agencies still ascribe to the notion that a premature release of uncertain information will cause undue worry and distress. However, we know that the exact opposite is true – people become more concerned if they discover that important information has been withheld, on the basis that they cannot trust agencies to provide them with timely information. Contrary to popular belief, most people are fully capable of understanding uncertainty and accepting that information may change, as knowledge about the risk situation improves. They are usually much more accepting of information that is continually updated than they are of information that is seen to be kept “secret” by risk agencies [12].

Communications should be balanced

Risk is seldom a “black and white” issue, with some chemicals or circumstances being universally “dangerous” and others being universally “safe”. Indeed, risk is more often an exercise in moderation. For example, consuming aspirin at accepted doses is acknowledged to be beneficial for everything from relieving pain to preventing heart attacks. However, at higher doses aspirin can be lethal. This is the basis of the toxicological principal first espoused by Paracelsus in the 1500s, “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy”. Despite this knowledge, communication about risks often focuses solely on the negative aspects of the risk, without acknowledging possible benefits. One of the most notable examples of this imbalance was in northern Canada, where indigenous residents were initially advised to stop eating their traditional food because of contamination with polychlorinated biphenyls (PCBs). It was later recognized that the benefits of consuming traditional foods (including, but not limited to, a greatly reduced rate of heart disease) needed to be balanced against the relatively small exposure to a toxic substance for which the risk information is still considered equivocal for cancer related effects [16].

Two-way communication involves listening as well as speaking

As noted elsewhere (*see Role of Risk Communication in a Comprehensive Risk Management Approach*), risk communication is now acknowledged to be “an interactive process of exchange

of information and opinion among individuals” that “raises the level of understanding of relevant issues or actions for those involved and satisfies them that they are adequately informed within the limits of available knowledge” [3, p. 2]. True two-dialogue cannot be achieved unless both parties are committed to listening and learning from diverse viewpoints.

People cannot communicate what they do not know or understand

This seemingly intuitive principle of risk communication was listed by Berlo [17] as one of the key elements of his “Source-Message-Channel-Receiver (SMCR)” model of communication. However, it is still an established practice in many agencies to relegate formal risk communication activities to people in their communication or public relations departments who have little specific knowledge of the more technical aspects of the risk. Conversely, if this responsibility is relegated to those with knowledge of the risk assessment process, they may lack knowledge of communication processes and considerations. Either situation usually results in confusion and frustration in risk communication efforts. Risk communicators need to both understand the technical aspects of the risk and have knowledge of risk communication processes.

Communication should be meaningful

If agencies embark on a risk communication process, they must be prepared to ensure that it is adequately and comprehensively conducted. If information on a risk is considered necessary for people to make informed decisions on a risk, then that information should be made available to all potentially affected people. For example, issuing information on a fish consumption advisory, but not ensuring that it reaches subsistent consumers of fish is not meaningful communication [12]. Likewise, involving people in a dialogue on risk means that agencies must be prepared to listen and learn from multiple viewpoints, and incorporate different types of knowledge into the risk discourse.

Agencies must accept responsibility for risk issues and devote adequate resources to their assessment and communication

Risk issues will never be adequately dealt with if no one assumes responsibility for their assessment, communication, and management [18]. This cannot be accomplished unless sufficient resources are made

available to do this in a comprehensive and sustained manner. In addition, responsible organizations must be careful to adequately balance their efforts and resource allocation. Most agencies, in dealing with risks, expend most of their resources on the technical assessment of the risks. However, the social discourse on risk is perhaps ultimately the most important component of risk management – if risk assessment information is not being adequately communicated and discussed in formulating appropriate risk decisions, ultimately it is for naught. Ideally, the resources devoted to the social management of risk should be equal to those devoted to the technical assessment of risks [19].

Summary

Successful risk communication will not occur serendipitously. Careful consideration must be paid to advance planning and to the many lessons that have been learned through previous (mostly unsuccessful) risk communication efforts. The considerations presented here may help in this process. However, it must be stressed that this list should not be considered either fully comprehensive or exhaustive. The best overall guidance is to try to view the risk through the eyes of those who may legitimately and rationally view the nature and consequences of the risk differently. Evoking an empathetic understanding of different perspectives of risk, together with the application of good judgment and plain old-fashioned common sense, is ultimately the key to initiating a productive dialogue on risks.

Continuous-Time Asset Allocation

Asset allocation (*see Actuary; Asset–Liability Management for Nonlife Insurers; Longevity Risk and Life Annuities*) is the distribution of one’s wealth among several securities so as to achieve a financial goal according to certain preferences or criteria. In a continuous-time environment, such a distribution is allowed to be rebalanced (*see Role of Alternative Assets in Portfolio Construction*) continuously over the entire investment horizon. Expected utility maximization (EUM) (*see Clinical Dose–Response Assessment*) and mean–variance (MV) portfolio (*see Scenario-Based Risk Management and Simulation Optimization; Risk Measures and Economic Capital for (Re)insurers; Extreme Value Theory in Finance*) selection, both in a given, finite investment horizon, are two predominant models for continuous-time asset allocation (*see Equity-Linked Life Insurance; Repeated Measures Analyses*). One of the two widely used approaches in the study of these models is formulating them as (dynamic) stochastic control problems (*see Role of Alternative Assets in Portfolio Construction*), and then solving them *via* standard control techniques such as dynamic programming, maximum principle, and linear–quadratic control. This approach is referred to as the *primal* or *forward* one, since it derives forward optimal strategies all at once. The other approach is to first identify the optimal terminal wealth (at the end of the horizon) by solving certain static optimization problems, and then finding optimal strategies by replicating the optimal terminal wealth. This is referred to as the *dual* or *backward* approach because the investment strategies are obtained in a reversed (in time) fashion, on the basis of the terminal wealth. This approach intimately relates to the hedging of contingent claims; and hence it reveals an inherent connection between asset allocation and hedging/pricing.

In this article, the primal and dual approaches in continuous-time asset allocation, for each of the EUM and MV models, are described.

The Market

Throughout this article, $(\Omega, \mathcal{F}, \mathcal{F}_t, P)$ is a filtered probability space (satisfying standard assumptions),

which represents the underlying random world and the progressive revelation of information with the passage of time. A standard m -dimensional Brownian motion (*see Insurance Pricing/Nonlife; Simulation in Risk Management*) $\{W(t); t \geq 0\}$, which is the source of the uncertainty, exists; it is assumed that $\mathcal{F}_t$ is generated by this Brownian motion. Also, the time horizon under consideration is $[0, T]$ throughout, where $T > 0$ is given and fixed.

Suppose there is a market in which $m + 1$ assets (or securities) are traded continuously. One of the assets is a *bank account* or a *bond* whose value $S_0(t)$ is subject to the following ordinary differential equation (ODE):

$$dS_0(t) = r(t)S_0(t) dt; \quad S_0(0) = s_0 > 0 \quad (1)$$

where the *interest rate* $r(t) \geq 0$ is a measurable and uniformly bounded function of t . The other m assets are *stocks* whose price processes $S_1(t), \dots, S_m(t)$ satisfy the following stochastic differential equation (SDE) (*see Statistics for Environmental Toxicity*):

$$dS_i(t) = S_i(t) \left[b_i(t) dt + \sum_{j=1}^m \sigma_{ij}(t) dW^j(t) \right];$$

$$S_i(0) = s_i > 0, \quad i = 1, 2, \dots, m \quad (2)$$

where $b_i(t)$ and $\sigma_{ij}(t)$ are respectively the *appreciation rates* and *dispersion* (or *volatility*) rates of the stocks. Once again, we assume that $b_i(t)$ and $\sigma_{ij}(t)$ are measurable and uniformly bounded functions of t .

Define the *volatility matrix* $\sigma(t) := (\sigma_{ij}(t))_{m \times m}$ and the *excess rate of return vector* $B(t) = (b_1(t) - r(t), \dots, b_m(t) - r(t))$. The basic assumption throughout is, for some $\delta > 0$ (*see Risk Attitude*),

$$\sigma(t)\sigma(t)' \geq \delta I, \quad \forall t \in [0, T] \quad (3)$$

Consider an agent whose total wealth at time $t \geq 0$ is denoted by $x(t)$. Assume that the trading of shares takes place continuously in a self-financed fashion, and transaction cost is not considered. Then $x(\cdot)$ satisfies the *wealth equation*:

$$dx(t) = [r(t)x(t) + B(t)\pi(t)] dt$$

$$+ \pi(t)' \sigma(t) dW(t); \quad x(0) = x_0 \quad (4)$$

where $\pi(\cdot) := (\pi_1(\cdot), \dots, \pi_m(\cdot))'$, with $\pi_i(t)$, $i = 1, 2, \dots, m$, denoting the total market value of the

agent's wealth in the i th asset at time t , is a *portfolio* or *investment strategy* of the agent.

A portfolio $\pi(\cdot)$ is called *admissible* if $\pi(\cdot)$ is $\mathcal{F}_t$ -progressively measurable and square integrable. Clearly, the SDE equation (4) has a unique solution $x(\cdot)$ corresponding to each admissible $\pi(\cdot)$, and we refer to $(x(\cdot), \pi(\cdot))$ as an *admissible (wealth–portfolio) pair*. The set of all admissible portfolios is denoted by Π .

Some preliminaries are in order. Define $\theta(t) = \sigma^{-1}(t)B(t)'$, the *market price of risk*, as well as a *pricing kernel* $\rho(\cdot)$ via the following SDE:

$$d\rho(t) = \rho(t)[-r(t)dt - \theta(t)'dW(t)]; \quad \rho(0) = 1 \quad (5)$$

Itô's formula shows that

$$x(t) = \rho(t)^{-1}E(\rho(T)x(T)|\mathcal{F}_t), \quad \forall t \in [0, T], \text{ a.s.} \quad (6)$$

and, in particular,

$$E(\rho(T)x(T)) = x_0 \quad (7)$$

which is termed the *budget constraint*. This single constraint is substituted for the dynamic budget constraint (the wealth equation), which also specifies the range of possible terminal wealth values (as random variables) induced by admissible portfolios, given the initial budget x_0 .

Expected Utility Maximization Model

In an EUM model, an agent makes asset allocation decisions based on some preferences, which are captured by a *utility function* $U(\cdot): \Re \mapsto \Re^+$, on the terminal wealth. This function is typically assumed to be concave, to reflect the *risk-averse* nature of a rational investor. More technical assumptions on $U(\cdot)$ (such as the *Inada* conditions) may be imposed in order for the EUM model to be solvable.

Given a utility function $U(\cdot)$ and an initial budget x_0 , the EUM is to

$$\begin{aligned} &\text{Maximize} && J_{\text{EUM}}(\pi(\cdot)) = EU(x(T)) \\ &\text{subject to} && (x(\cdot), \pi(\cdot)) \text{ admissible, satisfying} \\ &&& \text{equation (4).} \end{aligned} \quad (8)$$

The primal (forward) approach to solve the problem, which is essentially that of the stochastic control, is described first. Let v be the *value function* corresponding to equation (8), that is, $v(t, x)$ is the optimal value of equation (8) if the initial time is t (instead of 0) and the initial budget is x (instead of x_0). Then v satisfies the *Hamilton–Jacobi–Bellman* (HJB) equation:

$$\begin{cases} v_t + \sup_{\pi \in \mathbb{R}^m} \left(\frac{1}{2} \pi' \sigma \sigma' \pi v_{xx} + B \pi v_x \right) \\ \quad + r x v_x = 0, \quad (t, x) \in [0, T) \times \Re \\ v(T, x) = U(x) \end{cases} \quad (9)$$

The *verification theorem* in stochastic control dictates that the optimal portfolio (control) is the one that achieves the supremum above, that is,

$$\pi^*(t, x) = -(\sigma(t)')^{-1} \theta(t) \frac{v_x(t, x)}{v_{xx}(t, x)} \quad (10)$$

The above optimal strategy is expressed in a *feedback* form as a function of the calendar time t and the wealth x , which is easy to use (if v is known). To get v , plugging this expression back to equation (9) we obtain the following partial differential equation (PDE) that v must satisfy:

$$\begin{cases} v_t - \frac{1}{2} |\theta|^2 \frac{(v_x)^2}{v_{xx}} + r x v_x = 0, \\ \quad (t, x) \in [0, T) \times \Re \\ v(T, x) = U(x) \end{cases} \quad (11)$$

The solution to the above PDE depends on the choice of the utility function U , and could be obtained analytically for certain classes of utility functions. The general procedure of the primal approach is, therefore, (a) to solve PDE equation (11) first; and (b) to obtain the optimal feedback strategy π^* via equation (10).

The second approach, the dual (backward) one, involves the pricing kernel ρ defined by equation (5). In view of the budget constraint equation (7), one solves first a static optimization problem in terms of the terminal wealth, X :

Maximize $EU(X)$
 subject to $E[\rho(T)X] = x_0$; X is an
 $\mathcal{F}_T$ -measurable random variable (12)

This is a constrained convex optimization problem. To solve it, one introduces a Lagrange multiplier λ to eliminate the linear constraint, leading to the following problem

Minimize $E[U(X) - \lambda\rho(T)X]$ (13)

The solution is, obviously, $X^* = (U')^{-1}(\lambda\rho(T))$, where λ is determined in turn by the original constraint

$$E[\rho(T)(U')^{-1}(\lambda\rho(T))] = x_0 \quad (14)$$

The optimal portfolio to equation (8) and the corresponding wealth process can be determined by replicating X^* . This is realized by solving the following backward stochastic differential equation (BSDE) in $(x^*(\cdot), z^*(\cdot))$:

$$\begin{aligned} dx^*(t) &= [r(t)x^*(t) + \theta(t)'z^*(t)]dt + z^*(t)'dW(t), \\ x^*(T) &= (U')^{-1}(\lambda\rho(T)) \end{aligned} \quad (15)$$

and setting

$$\pi^*(t) = (\sigma(t)')^{-1}z^*(t) \quad (16)$$

Then $(x^*(\cdot), \pi^*(\cdot))$ is the optimal pair.

It remains to solve the BSDE equation (15). One way is to employ the so-called four-step scheme that, in the current setting, starts with conjecturing $x^*(t) = f(t, \rho(t))$ for some function f . Applying Itô's formula and noting equation (5), we obtain

$$\begin{aligned} dx^*(t) &= \left(f_t - r\rho f_\rho + \frac{1}{2}|\theta|^2\rho^2 f_{\rho\rho} \right) dt \\ &\quad - \rho f_\rho \theta' dW(t) \end{aligned} \quad (17)$$

Comparing the drift and diffusion terms between equations (15) and (17), we derive the following PDE that f must satisfy

$$\begin{cases} f_t + \frac{1}{2}|\theta|^2\rho^2 f_{\rho\rho} + (|\theta|^2 - r)\rho f_\rho - rf = 0, \\ (t, \rho) \in [0, T] \times \mathbb{R}^+ \\ f(T, \rho) = (U')^{-1}(\lambda\rho) \end{cases} \quad (18)$$

This is actually a *Black-Scholes equation* (see **Risk-Neutral Pricing: Importance and Relevance**;

Weather Derivatives) arising in option pricing. The optimal strategy is, therefore,

$$\begin{aligned} \pi^*(t) &= (\sigma(t)')^{-1}z^*(t) \\ &= -(\sigma(t)')^{-1}\theta(t)\rho(t)f_\rho(t, \rho(t)) \end{aligned} \quad (19)$$

To recapture, one carries out the following steps in the dual approach: (a) solving equation (14) to get λ ; (b) solving equation (18) to obtain the function f ; and (c) applying equation (19) to obtain the optimal strategy.

Mean-Variance Portfolio Selection Model

An MV model is to minimize the variance of the terminal wealth after a target expected terminal return is specified. Mathematically, it is formulated as a constrained stochastic optimization problem, parameterized by $a \geq x_0 e^{\int_0^T r(t) dt}$:

Minimize $J_{MV}(\pi(\cdot)) = \text{Var}(x(T))$
 subject to $Ex(T) = a$; $(x(\cdot), \pi(\cdot))$ admissible,
 satisfying equation (4) (20)

The optimal strategy of the above problem is called *efficient*.

To handle the constraint $Ex(T) = a$, we apply the Lagrange multiplier technique to minimize the following cost functional

$$\begin{aligned} J(\pi(\cdot), \lambda) &:= E\{|x(T)|^2 - a^2 - 2\lambda[x(T) - a]\} \\ &= E|x(T) - \lambda|^2 - (\lambda - a)^2 \end{aligned} \quad (21)$$

for each fixed $\lambda \in \mathbb{R}$.

To solve the preceding problem (ignoring the term $-(\lambda - a)^2$ in the cost), we use the *completion-of-square* technique common in stochastic linear-quadratic control. Applying Itô's formula we obtain

$$\begin{aligned} d \left[e^{-\int_t^T (|\theta(s)|^2 - 2r(s)) ds} \left(x(t) - \lambda e^{-\int_t^T r(s) ds} \right)^2 \right] \\ = e^{-\int_t^T (|\theta(s)|^2 - 2r(s)) ds} \\ \times \left[\left| \sigma(t)' \pi(t) + \theta(t) \left(x(t) - \lambda e^{-\int_t^T r(s) ds} \right) \right|^2 dt \right. \\ \left. + 2 \left(x(t) - \lambda e^{-\int_t^T r(s) ds} \right) \pi(t)' \sigma(t) dW(t) \right] \end{aligned} \quad (22)$$

Integrating in time and taking expectation, and employing a standard stopping time technique, we have

$$E|x(T) - \lambda|^2 \geq e^{-\int_0^T (|\theta(s)|^2 - 2r(s)) ds} \times \left(x_0 - \lambda e^{-\int_0^T r(s) ds} \right) \quad (23)$$

and the equality holds if and only if

$$\pi(t) = -(\sigma(t)')^{-1} \theta(t) \left(x(t) - \lambda e^{-\int_t^T r(s) ds} \right) \quad (24)$$

It remains to determine the value of λ . Notice we have shown above that the minimum value of $J(\pi(\cdot), \lambda)$ over Π for each fixed λ is $J^*(\lambda) = e^{-\int_0^T (|\theta(s)|^2 - 2r(s)) ds} (x_0 - \lambda e^{-\int_0^T r(s) ds}) - (\lambda - a)^2$. Hence the convex duality theorem indicates that the value of λ for solving equation (20) is the one that maximizes $J^*(\lambda)$, which is

$$\lambda = \frac{a - x_0 e^{\int_0^T [r(t) - |\theta(t)|^2] dt}}{1 - e^{-\int_0^T |\theta(t)|^2 dt}} \quad (25)$$

To summarize, the optimal strategy for solving equation (20) is given by equation (24) (which is actually in a feedback form), where λ is given by equation (25). Now, treating $Ex(T) = a$ as a parameter, we can easily obtain the optimal value of equation (20) as follows:

$$\text{Var}(x(T)) = \frac{1}{e^{\int_0^T |\theta(t)|^2 dt} - 1} \left[Ex(T) - x_0 e^{\int_0^T r(t) dt} \right]^2, \\ Ex(T) \geq x_0 e^{\int_0^T r(t) dt} \quad (26)$$

This gives a precise trade-off between the mean (return) and variance (risk) that an efficient strategy could achieve, in the classical spirit of Markowitz. Equation (26) gives rise to the *efficient frontier*. It is a straight line if plotted on a mean–standard deviation plane.

In addition to the primal approach depicted above, the MV model (20) can also be solved by the dual approach. Consider the following optimization problem in terms of the terminal wealth:

$$\begin{aligned} &\text{Minimize} \quad EX^2 - a^2 \\ &\text{subject to} \quad E[\rho(T)X] = x_0; \quad E[X] = a; \quad X \text{ is an} \\ &\quad \mathcal{F}_T\text{-measurable random variable} \end{aligned} \quad (27)$$

There are two constraints, calling for two Lagrange multipliers $(2\mu, -2\lambda)$ so that one solves

$$\text{Minimize}_{X \text{ is } \mathcal{F}_T\text{-measurable}} E[X^2 - 2\lambda X + 2\mu\rho(T)X] \quad (28)$$

The optimal solution to such a relaxed problem is $X^* = \lambda - \mu\rho(T)$, with the constants λ and μ satisfying

$$E[\rho(T)(\lambda - \mu\rho(T))] = x_0, \quad E[\lambda - \mu\rho(T)] = a \quad (29)$$

Since these equations are linear, the solution is immediate:

$$\begin{aligned} \lambda &= \frac{aE[\rho(T)^2] - x_0E[\rho(T)]}{\text{Var}(\rho(T))}, \\ \mu &= \frac{aE[\rho(T)] - x_0}{\text{Var}(\rho(T))} \end{aligned} \quad (30)$$

To obtain the replicating portfolio and the corresponding wealth process $(x^*(\cdot), \pi^*(\cdot))$, we use equation (6):

$$\begin{aligned} x^*(t) &= \rho(t)^{-1} E\left[(\lambda - \mu\rho(T))\rho(T) | \mathcal{F}_t\right] \\ &= \lambda e^{-\int_t^T r(s) ds} - \mu e^{-\int_t^T (2r(s) - |\theta(s)|^2) ds} \rho(t) \end{aligned} \quad (31)$$

A direct computation on the above, using equation (5), yields

$$\begin{aligned} dx^*(t) &= \left[rx(t) + \mu|\theta(t)|^2 \rho(t) e^{-\int_t^T (2r(s) - |\theta(s)|^2) ds} \right] dt \\ &\quad + \mu e^{-\int_t^T (2r(s) - |\theta(s)|^2) ds} \rho(t) \theta(t)' dW(t) \end{aligned} \quad (32)$$

Comparing the above with the wealth equation (4), we conclude that

$$\begin{aligned} \pi^*(t) &= (\sigma(t)')^{-1} \theta(t) \mu e^{-\int_t^T (2r(s) - |\theta(s)|^2) ds} \rho(t) \\ &= -(\sigma(t)')^{-1} \theta(t) \left(x^*(t) - \lambda e^{-\int_t^T r(s) ds} \right) \end{aligned} \quad (33)$$

This, certainly, agrees with equation (24) derived *via* the forward approach.

Notes

Bachelier [1] was the first to use Brownian motion to model the dynamics of security prices, whereas Mirrlees [2, 3] is probably the first to employ the Itô calculus to study continuous-time asset allocation. A continuous-time asset allocation model is significantly different from its single-period counterpart because the possibility of continuous trading effectively changes the investment set from one with a finite number of securities to one with an infinite number of attainable contingent claims [22]. The stochastic control (or forward/primal) approach described in the section titled “Expected Utility Maximization Model”, including the use of the HJB equation, was put forward and developed by Merton [4, 5] for solving EUM. Latest and comprehensive sources for general stochastic control theory and applications are Fleming and Soner [6] and Yong and Zhou [7]. Extensions following Merton’s method have abounded; refer to Duffie [8] and Karatzas and Shreve [9] for more historical notes. The backward/dual approach (also known as the *martingale approach*), described in the section “Expected Utility Maximization Model”, was developed by Harrison and Kreps [10], Harrison and Pliska [11], Pliska [12], Cox and Huang [13], and Karatzas *et al.* [14], except that in these works, the martingale representation theorem is used instead of BSDEs. This approach has its roots in Bismut [15, 16] who happens to be the father of the BSDE theory. (Interestingly, Bismut’s linear BSDE is originally wedded to the maximum principle in stochastic control – this shows an intrinsic connection between the primal and dual approaches in the context of asset allocation.) See Yong and Zhou [7] and Ma and Yong [17] for more on BSDEs (including extension to nonlinear BSDEs and the four-step scheme mentioned in the section “Expected Utility Maximization Model”) and the related historical notes, and Duffie [8] and Karatzas and Shreve [9] for more references on the dual approach for EUM. It is intriguing that the dual approach leads to a Black–Scholes type equation (18), which suggests a profound primal–dual relation between asset allocation and pricing. On the other hand, in a recent paper Jin *et al.* [18] have shown, through various counterexamples, that some of the standing assumptions in this approach, such as the existence of the Lagrange multiplier and the well posedness of the underlying model,

may not be valid, and sufficient conditions are presented to ensure the solvability of a general EUM model.

Markowitz’s (single-period) MV model [19] marked the start of the modern quantitative finance theory. Perversely enough, extensions to the dynamic – especially continuous time – setting in the asset allocation literature have been dominated by the EUM models, making a considerable departure from the MV model. While the utility approach was theoretically justified by von Neumann and Morgenstern [20], in practice “few if any investors know their utility functions; nor do the functions which financial engineers and financial economists find analytically convenient necessarily represent a particular investor’s attitude towards risk and return” (Markowitz, H. *Private communication*, 2004). On the other hand, there are technical difficulties in treating dynamic MV models, primarily that of the incompatibility with the dynamic programming principle owing to the variance term involved. Richardson [21] is probably the earliest paper that studies a faithful extension of the MV model to the continuous-time setting (albeit in the context of a single stock with a constant risk-free rate), followed by Bajoux-Besnainou and Portait [22]. Li and Ng [23] developed an embedding technique to cope with the nonapplicability of dynamic programming for a discrete-time MV model, which was extended by Zhou and Li [24], along with a stochastic LQ control approach described in the section titled “Mean–Variance Portfolio Selection Model”, to the continuous-time case. Further extensions and improvements are carried out in, among many others, Lim and Zhou [25], Lim [26], Bielecki *et al.* [27], Xia and Yan [28], and Jin and Zhou [29].

Following the Nobel prize winning work of Kahneman and Tversky [30], known as the *prospect theory* (PT), that brings human emotions and psychology into decision making, there have been burgeoning research interests in incorporating the PT into portfolio choice; nonetheless, they have been hitherto overwhelmingly limited to the single-period setting. There are only a couple of papers that deal with behavioral asset allocation in continuous time, including Berkelaar *et al.* [31] and Jin and Zhou [32]. The latter have obtained fairly explicit solutions for a general problem featuring both *S*-shaped utility functions and distorted probability.

Copulas and Other Measures of Dependency

The field of probability includes the study of a wide class of univariate probability functions. The class of multivariate probability functions is less well studied and is mostly restricted to the multivariate normal distribution and its related functions such as the multivariate t and the Wishart distributions. The invention and study of copulas are motivated by the need to enlarge the class of multivariate distributions.

Copulas were proposed by Sklar [1, 2] as invariant transformations to combine marginal probability functions to form multivariate distributions. The word “copula” comes from Latin and means to connect or join. Sklar introduced this word and concept for linking univariate marginal distributions to form multivariate distributions. Specifically, copulas are measures of the dependent structure of the marginal distributions. Sklar’s proposal for developing multivariate distributions was to first determine the univariate marginal distributions for the variables of interest, transform the marginal cumulative distribution functions (*cdf*) to uniform variables on the $[0,1]$ interval, and form the multivariate distribution using a copula, which is the multivariate distribution of uniform marginals.

Sklar’s Theorem for Continuous Marginal Distributions

Let $F_i(x_i)$ be the *cdf* for X_i $i = 1, \dots, n$, and let $H(x_1, \dots, x_n)$ be the multivariate *cdf* with marginal $F_i(x_i)$. Since the probability integral $U_i = F_i(x_i)$ is a uniform random variable on $[0,1]$, there exists a unique copula, which is the multivariate *cdf* of uniform random variables. Thus, $C(u_1, \dots, u_n)$ on the n dimensional cube $[0, 1]^n$ is the *cdf* so that all marginals are uniform. Therefore,

$$\begin{aligned} C(u_1, \dots, u_n) &= P(U_1 \leq u_1, \dots, U_n \leq u_n) \\ &= H(F_1^{-1}(u_1), \dots, F_n^{-1}(u_n)) \end{aligned} \quad (1)$$

Conversely,

$$\begin{aligned} H(x_1, \dots, x_n) &= C(F_1(x_1), \dots, F_n(x_n)) \\ &\text{for all } (x_1, \dots, x_n) \end{aligned} \quad (2)$$

Thus $H(x_1, \dots, x_n)$ is a multivariate distribution with marginals $F_1(x_1), \dots, F_n(x_n)$. Note that if $F_i(x_i)$ $i = 1, \dots, n$ are not all continuous, the copula is unique on the range of positive values for the marginal distributions.

Copulas as Measures of Dependence

Since most applications have been based on bivariate distributions, the following discussion will assume $n = 2$.

The importance of copulas is that they provide a general description of complex dependent structures among the variables. For the multivariate normal distribution, and more generally, the elliptical distributions, the correlation coefficient, ρ , measures the dependency of random variables as a pairwise measure of linear relationships. It is invariant for strictly increasing/decreasing linear transformations. The bivariate random variables (X_1, X_2) are strictly independent when $\rho = 0$. However, ρ is not invariant to more general transformations, it does not capture tail dependencies, nor is it defined for probability functions that do not have finite variances. Further, ρ does not describe dependent structure in nonelliptical multivariate distributions. A more general strategy for generating independent random variables is with a copula $C(u_1, u_2) = u_1 u_2$. Note

$$\begin{aligned} C(u_1, u_2) &= P(U_1 \leq u_1, U_2 \leq u_2) \\ &= u_1 u_2 \\ &= H(F_1^{-1}(u_1) F_2^{-1}(u_2)) \end{aligned} \quad (3)$$

so that

$$H(x_1, x_2) = F_1(x_1) F_2(x_2) \quad (4)$$

If the random variables are not independent, their relationship is summarized in the joint *cdf* $H(x_1, x_2)$ or, equivalently, with the two-dimensional copula

$$H(x_1, x_2) = C(F_1(x_1) F_2(x_2)) \quad (5)$$

Both parametric and nonparametric methods have been suggested in the literature for estimating copulas. Parametric methods are often based on the method of maximum-likelihood estimation and nonparametric procedures have been proposed, for example, by Genest and Rivest [3].

The normal copula is a popular copula for generating a bivariate normal distribution with correlation ρ . Let $\Phi(x_1)$ be the *cdf* of the standard normal distribution and let $\Phi_\rho(x_1, x_2)$ be the *cdf* of the standard bivariate normal and $\Theta_\rho(x_1, x_2)$ be the probability density function of the standard bivariate normal. Then,

$$\begin{aligned} C(u_1, u_2) &= \int_{-\infty}^{\Phi^{-1}(u_1)} \int_{-\infty}^{\Phi^{-1}(u_2)} \Theta_\rho(x_1, x_2) dx_1 dx_2 \\ &= \Phi_\rho(\Phi^{-1}(u_1), \Phi^{-1}(u_2)) \end{aligned} \quad (6)$$

Since many physical phenomena exhibit characteristics not described by a normal distribution such as skewness, fat tails, and outliers, the normal copula has been generalized to the form

$$C(u_1, u_2) = H_\delta(F_1^{-1}(u_1), F_2^{-1}(u_2)) \quad (7)$$

where the marginal distributions can come from different families of distributions and the dependent relationships between random variables may be more complex than linear correlation. For this reason, alternative methods of dependence have been studied.

The two most popular measures for Kendall's τ and Spearman's ρ that will be denoted as ρ_s . Both these measures lie in the $[-1, 1]$ interval for continuous random variables, can be written as a function of copulas (see Schweizer and Wolff [4]), and are invariant under monotone transformations applied to each marginal distribution. Also, for the bivariate normal, Pearson's correlation coefficient, ρ_p , relates these nonparametric measures as follows:

$$\rho_p = \text{Sin}\left(\frac{\pi}{2}\rho_s\right) \quad (8)$$

$$\rho_p = 2\text{Sin}\left(\frac{\pi}{6}\tau\right) \quad (9)$$

In fact, the normal copula is easily extended beyond the bivariate case because it is not restricted to a correlation matrix consisting of Pearson correlation coefficients (see Frees and Valdez [5]).

To digress, Johnson and Tenenbein [6] proposed a method for constructing continuous bivariate distributions with specified marginals and dependence measures based on Spearman's ρ_s and Kendall's τ .

Generating Copulas

Copulas are important for constructing multivariate distributions by providing measures of dependence

for combining marginal distributions. Archimedean copulas, described in Nelsen [7, Chapter 4], are a large class of copulas generated by an additive, continuous, decreasing convex function $\varphi(t)$ that maps t from the $[0, 1]$ interval, onto the $[0, \infty]$ range. Thus, a multivariate copula in this family can represent the association between variables with given marginal *cdf*'s by a univariate function. Copulas in this class are symmetrical, satisfying the relationship $C(u, v) = \varphi^{-1}(\varphi(u) + \varphi(v)) = C(v, u)$ where φ^{-1} is the inverse of the generator. Genest and Rivest [3] proposed a methodology for identifying $\varphi(t)$. The Archimedean copulas are easily constructed and appear in a simple closed form that allows for a wide variety of asymmetrical forms of tail distribution dependence. A discussion and listing of both bivariate and multivariate copulas in this class are available in Nelsen [7]. Thus, for example, using a linear combination of Archimedean copulas describing the dependency of two marginal t -distributions gives rise to a fat-tailed distribution with different tail dependencies. Canela and Collazo [8] propose using the *EM* algorithm, for determining weights to combine a Clayton copula that provides lower tail dependence with a Gumbel/Joe copula that provides upper tail dependence. Another procedure developed by Genest *et al.* [9] for developing asymmetrical copulas was based on developing a family of nonexchangeable bivariate copulas. These distributions play an important role in applications of extreme value theory to the study of risk; see Genest and Rivest [10]. Joe [11, Chapter 6] provides a summary of univariate extreme value theory with extensions to multivariate extreme distributions based on copulas (see **Extreme Value Theory in Finance**). This chapter concludes with unsolved problems in this area.

Frees and Valdez [5] presented a procedure for simulating outcomes from a multivariate distribution based on copulas. Then they illustrated their methodology for generating losses and expenses of insurance company indemnity claims that were subject to censoring.

The need for general measures of dependency is also apparent in the number of articles in this encyclopedia that are based on copulas; Dhaene *et al.* (see **Comonotonicity**) and Frees (see **Dependent Insurance Risks**) recommend copulas for modeling correlated risks as well as groups of individuals that are exposed to similar economic and physical environments. Wang (see **Credit Value at Risk**) uses

copulas to model joint default probabilities in credit portfolios, and Kapadia (*see Default Correlation*) modeled correlated default probabilities of individual firms. In a paper on simulation, McLeish and Metzler (*see Simulation in Risk Management*) proposed copula models of default times of individual obligors for studying credit risk. Other applications include modeling the probability survival of groups of individuals as well as modeling joint mortality patterns.

Correlated Risk

Correlated Risks from Natural Disasters

Correlated risk refers to the *simultaneous occurrence* of many losses from a single event. As pointed out earlier, natural disasters such as earthquakes, floods, and hurricanes produce highly correlated losses: many homes in the affected area are damaged and destroyed by a single event.

If a risk-averse insurer faces a highly correlated losses from one event, it may want to set a high enough premium not only to cover its expected losses but also to protect itself against the possibility of experiencing catastrophic losses. An insurer will face this problem if it has many eggs in one basket, such as providing earthquake coverage mainly to homes in Los Angeles rather than diversifying across the entire state of California.

To illustrate the impact of correlated risks on the distribution of losses, assume that there are two policies sold against a risk where $p = 0.1$, $L = \$100$. The actuarial loss for each policy is \$10. If the losses are perfectly correlated, then there will be either two losses with probability of 0.1, or no losses with a probability of 0.9. On the other hand, if the losses are independent of each other, then the chance of

two losses decreases to 0.01 (i.e., 0.1×0.1), with the probability of no losses being 0.81 (i.e., 0.9×0.9). There is also a 0.18 chance that there will be only one loss (i.e., $0.9 \times 0.1 + 0.1 \times 0.9$).

The expected loss for both the correlated and uncorrelated risks is \$20.^a However, the variance is always higher for correlated than for uncorrelated risks if each has the same expected loss. Thus, risk-averse insurers will always want to charge a higher premium for the correlated risk.^b

End Notes

a. For the correlated risk the expected loss is $0.9 \times \$0 + 0.1 \times \$200 = \$20$. For the independent risk the expected loss is $(0.81 \times \$0) + (0.18 \times \$100) + (0.01 \times \$200) = \20 .

b. For more details on this point and an illustrative example, see Hogarth and Kunreuther [1].

Cost-Effectiveness Analysis

This article presents economic evaluation, in particular, cost–effectiveness analysis (CEA), as a framework to approach and inform difficult decisions about the best use of limited resources. The article focuses on the requirements of a health care policy maker attempting to determine whether to reimburse a health care technology given the information and uncertainty surrounding the decision, and/or whether to request further research to inform the decision. The approach employs a decision analysis framework. The article starts with a brief discussion of welfare economics and cost–benefit analysis, before focusing on CEA. The article covers incremental cost–effectiveness ratios (ICERs) and decision rules for cost effectiveness, methods for handling and presenting uncertainty in cost effectiveness, and the use of value of information (VOI) methods for decision making (*see* **Decision Analysis**). The general approach and specific concepts are illustrated through the use of a stylized case study.

Welfare Economics: The Foundation of Economic Evaluation

In a resource-limited environment, it is important to determine whether a proposed health program represents a good use of scarce resources (money, labor, land, capital, etc.). Welfare economics provides a framework to address the issue of whether a proposed change is a good use of resources. It is founded on the view that individuals are welfare maximizers and are in the best position to assess their own welfare (consumer sovereignty). Proposed changes are judged in terms of welfare and a program change is deemed to be “better” if it improves social welfare. In the case where a program change makes at least one person better off and no one worse off (in terms of welfare), it is said to be a “Pareto improvement”. However, most program changes involve both gainers and losers. In this case, we ask whether the gainers could compensate the losers for their loss and still be better off (Kaldor compensation test) or if losers could compensate gainers to oppose the change and still be better off

(Hicks compensation test). In either case, there is a “potential Pareto improvement”. The compensation does not actually have to be paid for the change to be considered “better”. Implicitly this means that the current state of income distribution and the distributive impact of the program change are considered to be acceptable.

Economic evaluation is about identifying, measuring, and valuing what is given up (i.e., the costs of a program) and what is gained (i.e., the benefits of a program) in order to determine whether a program is a good use of resources. Cost–benefit analysis (CBA) involves individuals expressing their willingness to pay (in monetary terms) for the welfare changes (both positive and negative) associated with the proposed program. These valuations encapsulate all that is important to the individual, and all individuals whose welfare is affected are included within the process. The monetary valuations are then combined and compared to the costs associated with the change to determine whether the change is worthwhile. The major benefit of CBA is that, under the assumption that the distribution of income and impact of the change is acceptable, it is possible to determine that a program change is worthwhile *per se*, where the monetary valuation of the benefits exceeds the monetary value of the costs. CBA has been widely used within both environmental and transport economics to appraise projects such as road expansions, new airports, and environmental protection [1, 2]. However, within assessments of health care programs CBA has not been widely adopted although there are examples of applied CBA within the literature [3–7]. This is due mainly to the difficulty, value judgments, and ethical issues involved with asking individuals to assign monetary values to health care, which they are often not used to paying for.

Economic Evaluation in Health Care: The Move to Cost–Effectiveness Analysis

The more common view taken in the economic evaluation of health care is that of the extra welfarist. Here, health is considered to be the primary outcome of interest for health programs, an outcome so fundamental that individuals should receive it irrespective of their willingness to pay (known in economics as a *merit good*). With this approach, the societal objective becomes one of maximizing health gains (rather

than welfare) subject to the resource constraints. The methods of CEA are used to solve this constrained maximization problem. Within this framework, costs are measured in monetary terms and outputs are measured as utilities, typically using quality adjusted life years (QALYs). The aim with QALYs is to incorporate both the length and quality of remaining life, in order to reflect that a year in full health is not considered equivalent to a year in poor health. In calculating QALYs, the length of life is adjusted by a health-related quality of life score that reflects the quality of each year. Full health is usually represented by a quality weight of 1 with, for ease of calculation, death represented by a quality weight of 0. Sometimes natural units (e.g., life years) are used as a measure of output; however, this does not solve the constrained maximization problem.

In this framework, it is not possible to identify that a policy change is worthwhile *per se*. Instead, results are presented in terms of additional costs and additional outcomes associated with the program (compared to the alternative) to give a measure of the additional costs incurred, due to the program, for the additional health benefits secured [8–10]. This information is generally reported in the form of an ICER, although it can be provided graphically on the cost–effectiveness plane by plotting the costs against the effects for the program(s) investigated [11]. Equation (1) presents the ICER:

$$ICER = \frac{\text{Mean cost}_{\text{new program}} - \text{Mean cost}_{\text{current program}}}{\text{Mean QALY}_{\text{new program}} - \text{Mean QALY}_{\text{current program}}} \quad (1)$$

Figure 1 illustrates the cost–effectiveness plane. The plane is split into four quadrants by the origin (which represents the treatment comparator). The north east (NE) and south east (SE) quadrants involve positive incremental health effect associated with the treatment of interest, while the NE and north west (NW) quadrants involve positive incremental cost.

Decision Rules for CEA: Assessing Value for Money

A series of programs that apply to the same patient group, from which only one can be chosen, are

Figure 1 The incremental cost–effectiveness plane

mutually exclusive while programs that apply to different patient groups are independent (since any combination of programs can be implemented). ICERs are calculated relative to the next best, viable mutually exclusive programs; they are not calculated between independent programs. Programs are ranked in ascending order of cost, and ICERs are then calculated by dividing the additional cost by the additional health benefit involved with each successively more costly viable program [12]. On the cost–effectiveness plane, the slope of a line joining any two mutually exclusive programs denotes the ICER associated with moving from the cheaper to the more expensive program, and shallower slopes represent lower ICERs. Figure 2 illustrates an example of a series of fictional, mutually exclusive programs plotted on the cost–effectiveness plane.

On Figure 2, the program represented by point A is dominated by point B, which involves greater health benefits for a lower cost. Dominated programs should be identified and excluded from the analysis prior to calculating ICERs, to avoid spurious results. The program represented by point C is extended (or weakly) dominated, as it can be dominated by a mixed strategy involving programs B and D, represented by any point between M^1 (a strategy with identical health benefits to C that can be achieved at cheaper cost) and M^2 (a strategy involving identical costs to C that involves greater health benefits). The line OBDE presents a cost–effectiveness frontier, connecting all of the efficient programs.

Figure 2 Mutually exclusive programs on the CE plane

Having identified the ICERs for all the efficient programs that could be implemented, a decision must be made about which program should be implemented. Traditionally, the cost-effective program has been identified as the one that generates the largest ICER that falls below an externally set cost-effectiveness threshold (λ) [12]. This threshold (λ) represents the monetary value that the policy maker assigns to the health effect generated. It can be derived as the maximum price that society is willing to pay for health benefits or as the shadow price of health benefits [12]. Within the context of a budget-constrained health service (e.g., the National Health Service (NHS) in the United Kingdom), the second approach provides the theoretically appropriate method to maximize the health outcomes from a fixed budget. However, this method involves an enormous informational requirement in order to appropriately allocate the budget [13]. The first approach with its simple accept/reject rule is more convenient for decision making, but its employment requires explicit determination of the appropriate “fixed price” for health benefits.

The process of determining the ICER can be complex, particularly when a decision involves a choice between various mutually exclusive programs. However, by explicitly incorporating the cost-effectiveness threshold (λ) and rescaling the effects into a monetary value, the costs and effects can be combined to form a measure of net benefit for each program expressed in monetary terms (NMB)

[14–18]. Equation (2) illustrates the calculation of the NMB for a program (j).

$$NMB_j = (\lambda \times QALY_j) - Cost_j \quad (2)$$

The cost-effective program is now identified simply as that with the highest NMB.

Perspective

An important element of any economic evaluation is the perspective used to calculate costs and health benefits, as this affects the extent of the costs and consequences incorporated into the evaluation. Economists advocate a societal approach, which requires measuring and valuing the impacts of the program upon everyone who is affected by it. However, narrower, more manageable perspectives (e.g., that of the NHS) can be employed if value judgments are made that this perspective captures the majority of the important effects so that the extra effort required to get a societal perspective is not necessary. A frequently used perspective is that of the health care provider (e.g., NHS or health insurance company) for costs, and the individual patient for health benefits.

Incorporating Uncertainty

Economic evaluation is concerned with measures of cost effectiveness at the population level, the

expected costs and effects associated with the program change, rather than the impact on costs and effects at an individual patient level. As such, economic evaluation is primarily concerned with uncertainty rather than patient variability. Probabilistic sensitivity analysis can be used to convert uncertainty surrounding the model parameters into uncertainty surrounding the costs and effects. The process involves specifying a probability distribution for each of the basic parameters, those estimated directly from the evidence, within the model that are considered uncertain. The probability distribution represents the range of values that the parameter can take as well as the probability that it takes any specific value. In specifying the probability distribution, all information that is currently available for the parameter should be incorporated including any logical restrictions (for example, a probability must be restricted to the range 0–1). The next step involves propagating the parameter uncertainty through the model using Monte Carlo simulation. At each iteration, a value is selected from the probability distributions for each parameter and the model is recalculated. The cost and effect results for each iteration represent a realization of the uncertainty that exists in the model, as characterized by the probability distributions. Within the Monte Carlo simulation, this process is repeated a large number of times (usually > 1000) to generate a distribution of expected costs and effects associated with the program change.

Other types of uncertainty that may be important in an economic evaluation include methodological uncertainty (uncertainty surrounding the analytical methods used in the analysis e.g., discount rates) and structural uncertainty (uncertainty surrounding the structure and the assumptions used in the analysis e.g., method of extrapolation). Both of these can be assessed through the use of sensitivity analysis e.g., one-way sensitivity analysis, multiway sensitivity analysis, extreme analysis, or threshold analysis.

The uncertainty in costs and effects is most often presented as a scatter plot on the cost–effectiveness plane or summarized using a cost–effectiveness acceptability curve (CEAC). The CEAC illustrates the (Bayesian) probability that the program change is cost effective given the data and the alternative program(s) for a range of values for the maximum cost–effectiveness threshold (λ). The complement is the probability that the program change is not cost effective given the data and alternatives (the error

probability). For more details on CEACs for decisions involving multiple treatment alternatives and the link with the error probability, please see [19, 20].

Value of Information

Given an objective to maximize health subject to a resource constraint, a program change can and should be identified as cost effective simply on the basis of the expected values (ICER or NMB). However, owing to the inevitable uncertainty surrounding the estimates of costs and effects, there is a nonnegligible possibility that a decision made on the basis of the available information will be incorrect. Bayesian VOI analysis provides a framework to formally combine the error probability with the consequences associated with making an error to assess the expected opportunity losses associated with the existing (uncertain) evidence base and, thus, value further research aimed at reducing this uncertainty (*see Bayesian Statistics in Quantitative Risk Assessment*). The techniques involve establishing the difference between the expected value of a decision made on the basis of the existing evidence and the expected value of a decision made on the basis of further information [21–24]. This difference is then compared with the cost of collecting the additional evidence; where the value of further information exceeds the costs of collecting it, the research is deemed worthwhile [15].

Expected Value of Perfect Information

Perfect information surrounding all elements of the decision would, by definition, eliminate all uncertainty. It follows that the expected value of perfect information (EVPI) is equivalent to the expected cost of the current uncertainty surrounding the decision. Hence, estimating the costs of uncertainty surrounding a decision on whether to fund a program provides a measure of the *maximum* possible value for future research. This maximum value can then be compared with the cost of gathering further information to provide a necessary (but not sufficient) condition for determining whether further research is *potentially* worthwhile [15]. Research effort can then be focused on those areas where the cost of uncertainty is high and where additional research is potentially cost effective. As information provided by research is nonrival in consumption (i.e., once information

has been generated to inform a decision, it can be used to inform the decision for all patients without reducing the information available), the societal value of research (*see Societal Decision Making*) should be calculated across the population of potential program participants [14, 15].

The EVPI can be determined directly from the distribution of the mean costs and mean effects of the program change generated from the probabilistic sensitivity analysis. Each individual value in the distribution represents a possible future resolution of the current uncertainty (i.e., a possible future realization under perfect information) for which the appropriate intervention can be determined, on the basis of maximum NMB. As it is not known at which particular realization the uncertainty will resolve, the expected value of a decision with perfect information is calculated by averaging these maximum NMB over the distribution. The EVPI is then simply the difference between the expected value of the decision taken with perfect information (i.e., the expectation of the maximum NMB) and that taken with current information (i.e., the maximum of the expected NMB) [25] as illustrated in equation (3).

$$E_{\theta} \max_j NMB(j, \theta) - \max_j E_{\theta} NMB(j, \theta) \quad (3)$$

where j = programs and θ = parameters.

EVPI for Parameters. In addition to determining the EVPI for the entire decision, the techniques can be applied to direct research toward the elements of the decision where the elimination of uncertainty is of most value through the calculation of the EVPI for parameters (EVPPI). Here, the expected value of the decision with current information is the same as for the calculation of EVPI, but the calculation of the expected value of the decision with perfect information is more computationally intensive. It involves two stages. The first involves determining the expected value of the decision on the basis of the remaining uncertainties and the resolved parameters, in the same way as the expected value of the decision with current information is calculated for the EVPI (i.e., on the basis of the maximum expected net benefits). However, as the actual value(s) that the parameter(s) resolve(s) at is unknown, this calculation must be undertaken for each possible realization of the uncertainty in the parameter(s) (i.e., for each possible value in the

distribution). The expected value of the decision with perfect information about the remaining uncertainties is then taken as the expectation of these values, in a process similar to the calculation of the expected value with perfect information [25]. Equation (4) illustrates the calculation of the EVPPI.

$$EVPPI = E_{\varphi} \max_j E_{\omega|\varphi} NMB(j, \theta) - \max_j E_{\theta} NMB(j, \theta) \quad (4)$$

where j = programs, θ = parameters, φ = parameter (s) of interest, and ω = other parameters.

Expected Value of Sample Information (EVSII)

Perfect information is not obtainable with a finite sample size, and the EVPI only provides a necessary but not sufficient condition for undertaking research to reduce uncertainty. Determining the worth of specific research requires a method to value the reduction in uncertainty actually achievable through research. This method is provided through the expected value of sample information (EVSII). Where the EVSI outweighs the costs associated with the research, there is a positive expected net benefit of sampling (ENMBS). In this situation, the specific research is considered worthwhile *per se* [15, 25].

The EVSI depends upon the extent to which uncertainty and the associated consequences are actually reduced by the information provided from research (the informativeness of the research) and is a function of the specifics of the research (e.g., sample size and allocation; length of follow-up; and endpoints of interest). For more details see [15, 25].

Case Study: Uncomplicated Urinary Tract Infection in Adult Women

The Model

The case study is a stylized representation of a decision involving different strategies for managing nonpregnant, adult women presenting to general practice with the symptoms of uncomplicated urinary tract infection (UTI) (frequency, dysuria, urgency, and nocturia). It has been adapted, for the purposes of presentation, from previous analyses undertaken by Fenwick *et al.* [26, 27]. The first strategy involves empiric antibiotic treatment on

presentation of symptoms. The remaining strategies involve the use of diagnostic tests to exclude or confirm the presence of UTI prior to antibiotic treatment, either through a near-patient dipstick test generating immediate results; or a laboratory test, involving an overnight urine culture. Furthermore, with the laboratory test, diagnosis can be delayed to allow for additional sensitivity testing. This delays treatment but better targets the antibiotics to the specific bacteria. In all, there are seven different strategies for managing these patients, including no treatment, which are detailed in Table 1.

Figure 3 presents the decision model. A proportion of the women who present with symptoms of UTI in general practice will have other disorders. Each patient management strategy branch is modeled by splitting the symptomatic population according to the

presence of UTI, using information from prevalence studies [28]. A lack of quantitative information of other possible causes of symptoms in this group has led to all non-UTI cases being treated identically within the model. The assumption is made that those with non-UTI will not benefit from any of the strategies considered, and the only possible health outcome for these patients is that symptoms will persist. However, as these patients are not immediately identifiable, resources are still used in the management of their symptoms and these are included within the analysis of each strategy.

Uncomplicated UTI tends to be a self-limiting condition, with 50% of cases resolving naturally after 3 days [29] with the remainder resolving after an average of a week [30]. Where no treatment is given to patients with UTI, either as a deliberate strategy

Table 1 Strategies employed within the model of UTI management^(a)

Strategy name	Strategy description
No treatment (N)	GPs provide general advice on relieving symptoms and inform patients that symptoms will resolve within 7 days.
Empiric treatment (E)	All individuals presenting with symptoms of UTI receive a 3-day course of general antibiotics.
Empiric treatment plus laboratory test (EL)	The laboratory test is used to supplement empiric treatment. While all patients provide a urine sample for testing, during the initial consultation, the results only affect the management of those patients with persistent symptoms. For these patients antibiotic sensitivity results will be available at the second visit to the GP for those who tested positive, which will enable the GP to prescribe a course of specific antibiotics. This gives the patients with UTI who test positive a second chance for treatment with antibiotics to clear the infection. Antibiotics will not be altered on the basis of the sensitivity results until the second consultation.
Dipstick and treatment (D)	The dipstick test is employed at the initial consultation to provide an indication of presence of disease and to restrict the use of antibiotics to those considered most likely to have UTI, as denoted by the result of the dipstick test.
Dipstick and treatment plus laboratory test (DL)	The laboratory test is used to supplement the dipstick test. While all patients with a positive dipstick result provide a urine sample for further testing during the initial consultation, the results only affect those patients with persistent symptoms. For these patients antibiotic sensitivity results will be available at the second visit to the GP for those who tested positive, which will enable the GP to prescribe a course of specific antibiotics. This gives the patients with UTI who test positive a second chance for treatment with antibiotics to clear the infection. Antibiotics will not be altered on the basis of the sensitivity results until the second consultation.
Laboratory test and wait for preliminary results (LW)	All patients provide a urine sample at the initial consultation and treatment is determined by the positive/negative result of this test. Hence treatment is delayed until this result is available.
Laboratory test and wait for sensitivities (LS)	All patients provide a urine sample at the initial consultation and treatment is determined by the sensitivity result of this test. Hence treatment is delayed until the results of the sensitivity analysis are available. As a result, specific antibiotics are given to every confirmed case of UTI as a first treatment, leaving no secondary course of treatment for those with persistent symptoms.

^(a) Reproduced from [26]. © Royal College of General Practitioners, 2000

Figure 3 The patient management decision – UTI model [Reproduced from [26]. © Royal College of General Practitioners, 2000.]

or as the result of an incorrect test result, symptoms are assumed to either disappear after 3 days or to persist for 7 days (tree 1). Where UTI is the cause, the period of symptoms can be reduced through the use of antibiotics, which may resolve symptoms after 2 days from the start of the course [29]. The assumption is made that the use of antibiotics has no impact upon the probability of natural resolution, so where antibiotics are given symptoms may resolve naturally or as a result of the antibiotics, or may persist (tree 2).

When used, test results dictate the subsequent management of the patient. Treatment with antibiotics (and possibly a confirmatory laboratory culture) follows a positive result and no further treatment follows a negative one. When laboratory tests are undertaken, an initial positive/negative result can confirm the presence/absence of UTI and further analysis of positive results provides details of bacterial sensitivities that can direct prescribing. Where available, this information is used to manage patients in whom symptoms persist.

Patients given antibiotics are assumed to comply fully with the course of treatment. Eight percent are expected to experience side effects due to the antibiotics [31], which prolong the period of symptoms by an additional 2 days [32]. The assumption is made that there is no worsening of symptoms or progression to pyelonephritis due to withholding or delaying antibiotic treatment within this patient population.

This model deals with the primary management of uncomplicated UTI in women. As such, subsequent investigations in those whose symptoms persist following the completion of the management strategy are considered to be outside the scope of the model. Therefore, while patients are assumed to return to the general practitioner (GP) where symptoms persist, and the resources associated with these visits are included within the model, any further investigations are excluded from the model.

Tables 2 and 3 detail the probability distributions and data used to populate the model. Beta distributions [33] were used to represent the uncertainty concerning each of the probabilities within the model. The beta distributions were characterized using an α and β value taken from available trial data (α represents the number of patients experiencing the event and β the number not experiencing the event). For the sensitivity and specificity parameters of the dipstick, data from more than one trial was used to specify the distributions. Here the numbers of patients experiencing/not experiencing the event were added across trials to obtain the α and β values.

The event time parameters were represented as lognormal distributions, due to their positive nature and positive skew [40], characterized using a mean value and a standard error. The disutility values associated with symptoms and side effects were also represented by lognormal distributions characterized using the mean and standard error (taken as a

Table 2 Parameters for the β distributions for probability

Parameter	Base value (%)	α	β	References
Probability of UTI given symptoms	47	51	58	[28]
Sensitivity of dipstick	92	185	16	Combined data from [34, 35]
Specificity of dipstick	88	640	91	Combined data from [35, 36]
Sensitivity of laboratory test	99	104	1	Assumption
Specificity of laboratory test	99	104	1	Assumption
Probability that symptoms will resolve naturally given UTI	50	40	40	[29]
Probability that antibiotics will resolve symptoms given UTI	91	88	9	[37]
Probability that specific antibiotics will resolve symptoms given UTI	92	69	6	[38]
Probability of side effects due to antibiotic treatment	9.2	17	211	[31]
Proportion of patients suffering with continued symptoms who return to the GP when no treatment was given at initial visit	5	5	95	Assumption
Proportion of patients suffering with continued symptoms who return to the GP when treatment was given at initial visit	70	7	3	Assumption

Table 3 Parameters for the lognormal distributions for event times and disutility

Parameter	Base value	SE	References
Period of UTI infection	7	2	–
Time for antibiotics to work	2	0.6	–
Time for infection to clear up naturally	3	0.6	–
Time for laboratory test results	2	0.4	–
Time for sensitivity tests to be available	1	0.4	–
Duration of side effects	2	0.6	–
Disutility associated with persistent dysuria	0.2894	0.0724	[39]
Disutility associated with side effects	0.2894	0.0724	[39]

quarter of the mean value). Unit costs were taken from published sources including the British National Formulary and Unit Costs of Health and Social Care. Probability distributions were not assigned to the unit costs as these were considered to be variable rather than uncertain.

Results

On the basis of expected values, the least costly strategy is no treatment (N), generating an expected 0.99513 QALYs per episode of UTI at an expected cost of £8.93. The next least costly strategy involves testing with a dipstick followed by empiric treatment for positive results; this provides an expected 0.99601 QALYs per episode of UTI (an increase of 0.00088 QALYs) at a cost of £12.40 (an increase of £3.47). Thus, the dipstick strategy (D) involves an additional cost of £3492 per additional QALY (ICER). The next least costly strategy involves empiric treatment for all patients; this provides an expected 0.99603 QALYs per episode of UTI (an increase of 0.00002 QALYs) at a cost of £12.50 (an increase of £0.10). Thus, the empiric strategy (E) involves an additional cost of £4438 per additional QALY (ICER). Finally, the empiric plus laboratory (EL) strategy provides an expected 0.99606 QALYs per episode of UTI (an increase of 0.00003 QALYs) at a cost of £15.22 (an increase of £2.73). Thus, the EL strategy involves an additional cost of £14 500 per additional QALY (ICER). The two strategies employing laboratory testing prior to treatment both generate fewer QALYs at a higher cost than empiric treatment and are dominated. The strategy with a confirmatory laboratory test following a dipstick test (DL) is more effective than the empiric strategy but has a higher ICER than the EL strategy and is extended dominated. The

choice between the patient management strategies will depend crucially upon the value that the policy maker is willing to pay for additional QALYs in this patient group.

Figure 4 presents the cost–effectiveness plane for the seven management strategies illustrating the expected values for costs and effects. The uncertainty in the estimates is not shown on this figure as the cost–effectiveness plane becomes unmanageable and indecipherable with this number of interventions. Figure 5 illustrates the CEACs for the management strategies, although only five are visible over this range of values of λ . The figure shows that when the policy maker was unwilling to pay anything for an additional QALY the probability that no treatment was optimal is 1. If the policy maker was willing to pay £20 000 per QALY gained, empiric treatment (E) is considered cost effective on the basis of expected values. The probability that empiric treatment was cost effective at this value of the cost–effectiveness threshold is 0.573. These probabilities for no treatment (N), EL, and the dipstick strategy (D) are 0.016, 0.012, and 0.383 respectively. If the policy maker was willing to pay £30 000 per QALY gained, the probability that empiric treatment was cost effective is 0.544, with those for the no treatment (N), EL, and the dipstick strategy (D) being 0.009, 0.045, and 0.347 respectively. This indicates that there is considerable uncertainty surrounding the decision between the methods of patient management. For a cost–effectiveness threshold value of £20 000 per additional life year, the uncertainty (i.e., probability of making the wrong decision) associated with the choice of empiric treatment (E) is 0.427. This is much higher than would be acceptable by standard conventions of significance.

Figure 4 Cost-effectiveness plane – UTI model

Figure 5 Cost-effectiveness acceptability curves – UTI model

The EVPI was calculated to be £0.30 per case of UTI, given a cost-effectiveness threshold of £20 000 per QALY, or £0.46 per episode for a cost-effectiveness threshold of £30 000 per QALY. These values translated into a population EVPI of £2.3 or £3.6 million respectively (see Figure 6). These values provide absolute limits on the worth of further research concerning all elements of the decision, for these values for the cost-effectiveness threshold. Thus, further research costing less than £2.3 million (£3.6 million) is potentially worthwhile, assuming that the cost-effectiveness threshold is £20 000 (£30 000) per QALY. A partial EVPI analysis

illustrated that further research should concentrate upon getting better estimates of disutility values, rather than prevalence data for UTI or side effects. Given that the problem of selection bias is not expected to be important in the estimation of disutility parameters, it would not be necessary to undertake a clinical trial.

Conclusion

This article has introduced economic evaluation for health care decision making and shown how decision analysis can be a useful tool for economic evaluation.

Figure 6 Expected value of perfect information for the decision (UK population) versus the uncertainty cost-effectiveness acceptability frontier (CEAF)

Within the case study, the techniques provided the cost effectiveness and uncertainty associated with each of the various methods of patient management. The EVPI analysis illustrated that there was worth in conducting further research, in particular, with respect to disutilities. Given that the problem of selection bias is not expected to be an important issue in the estimation of disutility parameters, it would not be necessary to undertake a clinical trial. As such, a decision model incorporating VOI analysis could be employed to improve the efficiency of health technology assessment. However, in order to use these techniques appropriately, it is important that the decision model captures and incorporates all of the available evidence, rather than relying on the best estimate. In addition, it must be remembered that any probabilistic analysis and/or VOI analysis is only as good as the underlying model on which it is based.

Counterterrorism

No one who has seen them can forget the video images of airplanes hitting the twin towers of the World Trade Center on September 11, 2001. Terrorist acts, even those directed at or taking place within the United States, had occurred previously, but worldwide a new sense of vulnerability has arisen. Arguably, since 2001 there has been little diminution of terrorist actions: examples include the 2004 train bombings in Madrid, the 2005 attacks on the London underground, and endemic violence in the Middle East.

Counterterrorism (see **Managing Infrastructure Reliability, Safety, and Security; Game Theoretic Methods; Sampling and Inspection for Monitoring Threats to Homeland Security**) is the process of forestalling or mitigating the consequences of terrorist acts by acquiring advance knowledge of them, intervening before they can take place, and minimizing human, economic, and other impacts should they occur. Because so much of the process is conducted in secret by governments, it is not possible in this encyclopedia to provide details. Instead, this article outlines some of the dimensions and complexities of countering terrorist plots, and discusses how terrorist risk relates to other risks. Counterterrorism is one of many settings in which the realities of risk and the perception of risk may be inconsistent. In the United States and elsewhere, broad-based counterterrorism strategies address both reality and perception.

What is Counterterrorism?

Defining terrorist acts (see **Human Reliability Assessment**) may be impossible, but most people would identify terrorist acts to have some or all of the following characteristics:

- They take place (spatially and temporally) outside of “ordinary” military conflicts, and may be committed for nonmilitary (for example, religious or political) reasons.
- They target civilians rather than the uniformed military.
- They are committed by small groups or individuals who are often willing to die in the process.

- Overt or implicit support by a legitimate national state is not necessary, but may be present.
- They are, by design, unpredictable.
- They are specifically meant to inspire consequences such as fear and economic or political disruption.

As compared with ordinary military conflicts, terrorist acts are complex, heterogeneous, and geographically dispersed to point that they may be seen (and may be meant to be seen) as essentially random. Pan Am Flight 103 exploded over Lockerbie, Scotland, in 1988 as the result of a (state-sponsored) terrorist act. Four days previous to that, this author was on a TWA flight from Frankfurt to the United States from which luggage had to be removed because its owners had not boarded the flight. It is impossible not to ask “What if?” As suggested in the introductory text, counterterrorism [1, 2] can be thought of as having the following five principal components:

Information

Advance knowledge is the only basis for preventing terrorist acts, at least within our current legal framework, which does not allow action without information against those who “might” commit terrorist acts. Significant parts of the process and the results are classified, but the wealth of information turned up *ex post facto* about the 9/11/01 airplane hijackers leads to tantalizing feelings that the answer is also there beforehand, if only we could find the “needle in the haystack”.

Intervention

Given sufficient, and sufficiently credible, information that a terrorist act may occur, a government can intervene to prevent it. This author does not know the specifics of intervention strategies. It appears that, depending on situational factors, a successful intervention may or may not be made public.

Deterrence

Every counterterrorism strategy (indeed, it seems any strategy to combat any unlawful behavior) must involve deterrence mechanisms. These mechanisms may operate well before the fact (“We are watching you”), at the time and place of an intended act (physical barriers, searches of air passengers’ possessions), and after the fact (“You will be identified, tracked down, and punished”).

Mitigation

It is not prudent to believe that deterrence, information, and intervention will always succeed. Counterterrorism strategies also include steps to mitigate effects should a terrorist act occur. These range from the physical (building escape routes, isolation strategies for infected animal herds) to the operational (intercommunication among first responders) and beyond.

Control of consequences

Because terrorist acts are meant to have consequences beyond the immediate, these must be addressed as well. For instance, introduction of foot-and-mouth disease into cattle in the United States might, given effective interventions, lead to the isolation or destruction of a few hundred animals. Nevertheless, because of fear (In fact, foot-and-mouth disease is quite harmless to healthy humans.), an ensuing economic dislocation on the order of \$1 billion or more could occur.

One uniquely complicated consequence – risk perception – is discussed in the section titled “Perception *versus* Reality”.

Perception *versus* Reality

A disclaimer: what follows is in no sense meant to downplay the horrific events of 9/11/01, but only to illustrate the complexity of the issues. Terrorists have succeeded in their objective to instill fear, with resultant economic and political dislocations, in significant part because of public perception of risk [3].

Approximately 3000 people died in the attacks on 9/11/01. That same month, 3555 people died in automobile crashes in the United States (and 42 196 for the entire year of 2001). In 2001, 29 573 people in the United States died from gunshot wounds. Less than 1/10th as many people died in the United States in 2001 from anthrax attacks than from being hit by lightning. Yet, reaction to perceived terrorist risks far exceeds that to far greater (and more widespread) other risks. One (seemingly easily) thwarted attempt to detonate an explosive device in a shoe led to immense cost, lost time, and inconvenience from people removing their shoes in airports. Nor is there public evidence that this precaution has prevented any further attacks.

Risk perception is an enormously complex phenomenon, of which inconsistency may be the only consistent characteristic. To illustrate, driving is more dangerous than flying by 2 orders of magnitude in terms of population-level death rates, yet many more people fear the latter. Factors that feed such feelings include control (“I am in control of my car, so I can avoid accidents”), severity/certainty of consequences (“Everyone is killed in a plane crash, but many people survive automobile accidents”), and media visibility (All airplane crashes make the television news, but only the worst automobile accidents do), as well as the practical (“I can’t not drive, so why worry, and in any case I drive carefully”). All of these, and others, notably unpredictability, apply in terrorist settings.

Because risk perception is inherently inconsistent or even palpably irrational, counterterrorism strategies cannot ignore it. Perhaps removing shoes at the airport reduces fear more than it prevents terrorist attacks, but it is still legitimately part of a counterterrorism strategy. But, perception also adds to the already incredible complexity of the problems. Returning to an earlier illustration, automobile fatalities in United States in September, 2001 increased as compared to previous years (although not enough to vitiate the point of the second paragraph of this section) because of fear of flying resulting from the 9/11 attacks (and the impossibility of flying for several days thereafter). Increased perceived risk of one mode of transportation increased the actual risk of another.

Other Risks

The political debate and public conversation about risk and counterterrorism are dominated by the risk of occurrence of terrorist acts. However, consistent with the nature of the problem, there are multiple other risks, some of which are controversial.

While they may be impossible to quantify, risks associated with *false positives* – believing and acting on the belief that a person is a terrorist who in fact is not – exist and are unavoidable. Some researchers fear that analytical processes (one example: data mining of massive, disparate databases) that are powerful enough to detect terrorist attacks beforehand will be overwhelmed by false positives. (When you do not know what a needle looks like, how do you find one in a mile-high haystack?) In the United

States, the public has tolerated the hitherto fairly small numbers of false positives. If the number of false positives increases dramatically, that tolerance will diminish.

The information assembly and analysis aspect of counterterrorism carries other risks. Many people, across a political spectrum, believe that there is real – there surely is perceived – risk from the government’s access to intimate personal details (*see* **Coding: Statistical Data Masking Techniques**) (where one travels, what one buys, with whom one associates, what books one reads) in the process of searching for terrorists. Some counterterrorist initiatives, notably the Total Information Awareness project of the Defense Advanced Research Projects Agency, have been halted because of public outcry over these risks. Not surprisingly, exactly what the risks are and how big they are is more elusive. The major perceived risks are generic loss of privacy and the possibility that information will be used for purposes other than counterterrorism. How well-founded the fears are now, let alone in the future, is impossible to say, in large part because of lack of experience and data.

Counterterrorism as Risk Analysis

Whether counterterrorism is amenable to extant or foreseeable methods for quantitative, or even qualitative, risk analysis is a difficult question.

Some factors suggest that it is not. One example was discussed in the section titled “Perception *versus* Reality” – factors associated with perception. Perceived risks, in general, defy analysis. But might the risk of terrorist acts, as opposed to the consequences of those acts, be assessed independently of perception? Issues then arise that range from the conceptual to the practical. How (that is, using what data and what models) can we assess the risk of something that has never occurred, and which we may not even be able to define? There is strong suspicion on the part of some people that while it might be possible to characterize and prevent recurrences of acts that have been committed, this is missing the point. Terrorist organizations are not bureaucratic behemoths, and if one path of attack (physical entry into aircraft cockpits) is precluded, another (subverting pilots or baggage handlers or aviation fuel suppliers) will be found. No one could reasonably have estimated the

probability of anthrax being distributed in the mail in 2001, and no one may be able to do so now. “Impossible” may be the most defensible estimate.

Simply knowing that terrorist attacks have occurred may also become an issue. Because of the “fear” objective discussed in the section titled “What is Counterterrorism?”, terrorists often proclaim publicly – and sometimes falsely – responsibility for their acts. At some point uncertainty (Was yesterday’s collapse of the Internet a hardware failure or a terrorist act?) may become the behavior of choice. Were this to happen, the already significant paucity of reliable data may become insuperable.

Indeed, data availability and quality are likely to remain impediments for the foreseeable future to research in risk analysis as it relates to counterterrorism. It is, of course, not possible to make classified information available to the public, but in the absence of data, many analyses are speculative and most lack scientific verification.

Solid evidence is lacking, but there is indication in the United States of unwillingness to balance risks and benefits in a counterterrorism setting. Public (and political) attitudes about risk and benefit already vary wildly. The risk of being one of over 40 000 automobile accident victims is balanced in Congress and elsewhere against the benefits of using automobiles, and there is understanding that the cost of some solutions (e.g., making cars into 1 mile/gallon tanks that are impervious to crashes) exceed the benefits. On the other hand, the public stands willing for drugs that may be beneficial to millions of people to be removed from market in light of a handful of adverse incidents, not all of which can be linked causally to use of the drug.

Counterterrorism currently seems to lie closer to the latter. As benefits the most noble aspirations of a society, individuals have been willing to accept (not insignificant) personal costs in return for social benefits. Whether this will change if terrorism were no longer in the public eye remains to be seen. Currently, there appears to be little public will to deal in a principled manner with false positives, but this also may change.

Credibility Theory

Credibility theory (*see* **Insurance Pricing/Nonlife**) refers to a body of techniques actuaries use to assign premiums to individual policyholders in a heterogeneous portfolio. These techniques are applicable in fields other than insurance wherever one needs to distinguish between individual and group effects in a set of nonidentically distributed data. As such, credibility theory is sometimes defined shortly as “the mathematics of heterogeneity”.

With origins dating back to 1914, credibility theory is widely recognized as the cornerstone of casualty actuarial science (*see* **Dependent Insurance Risks; Reinsurance; Securitization/Life**). It is divided in two main approaches, each representing a different manner of incorporating individual experience in the ratemaking process (*see* **Nonlife Loss Reserving**). The oldest approach is limited fluctuations credibility, where the premium of a policyholder is based solely on its own experience, provided its experience is stable enough to be considered fully credible. The theory behind limited fluctuations credibility is rather simple and the technique has few correct applications, so it will be reviewed only briefly in this article.

The second approach concentrates on the homogeneity of the portfolio rather than the stability of the experience to determine the best premium for a policyholder. In greatest accuracy credibility, individual experience is taken into consideration only if it is significantly different from that of the portfolio. The more heterogeneous the portfolio, the more important becomes individual experience, and *vice versa*.

Experience Rating

The first concern of an insurer – whether a public or a private corporation – when building a tariff is to charge enough premiums to fulfill its obligations. For various reasons, including competitiveness, the insurer may then seek to distribute premiums fairly between policyholders. A classification structure (for example: according to age, sex, type of car, etc.) is usually the first stage in premium distribution. Experience-rating (*see* **Risk Classification in Nonlife Insurance**) systems, in general, and credibility methods, in particular, then constitute an efficient second stage.

As the name suggests, an experience-rating system takes the individual experience of a policyholder into account to determine its premium. Such systems require the accumulation of a significant volume of experience. Experience rating is thus especially used in workers compensation and automobile insurance.

On a more formal basis, Bühlmann [1] proposes the following definition:

Experience rating aims at assigning to each individual risk its own *correct premium* (rate). The *correct premium* for any period depends exclusively on the (unknown) claims distribution of the individual risk for this same period.

Example 1 Consider this simplified example (more details are presented in [2] or [3]): a portfolio is composed of ten policyholders and each policyholder can incur at most one claim of amount 1 per year. Before observing any experience for this portfolio, the insurer considers the policyholders equivalent on a risk level basis. Expecting that, on average, the portfolio will incur two claims per year, the insurer charges an identical premium of 0.20 to each policyholder. This is the collective premium.

The experience for this portfolio after 10 years is shown in Table 1. The insurer observed a total of 23 claims, for an average cost per policyholder of $23/100 = 0.23$. However, these 23 claims are not uniformly distributed among policyholders: policyholders 7, 8, and 10 incurred no claims, while policyholder 9 alone incurred seven.

Table 1 Experience of the simplified portfolio of Example 1 after 10 years

[illegible]

Therefore, the collective premium in this example is globally adequate, but clearly not fair. To avoid antiselection, the insurer should charge more to some policyholders and less to others. Experience showed that the portfolio is, to some degree, heterogeneous.

One could very well restate this example in a context other than insurance. The data of Table 1 merely establish whether an “event” occurred or not in 10 “trials” and for 10 different “subjects”. The goal is then to estimate the probability of occurrence for trial 11 for each subject, knowing that the subjects are not “equivalent”.

There exist numerous experience-rating systems, including bonus–malus and merit–demerit systems, participating policies or commissions in reinsurance [1, 4, 5], but the most widely used methods are credibility models.

Limited Fluctuations Credibility

Limited fluctuations credibility originated in the early 1900s with Mowbray’s paper “How Extensive A Payroll Exposure Is Necessary To Give A Dependable Pure Premium?” As the title suggests, Mowbray was interested in finding a level of payroll in workers compensation insurance for which the pure premium of a given employer would be considered fully dependable or, in other words, fully credible.

We may believe that this question arose from one or a few large employers requesting from their insurer to pay a premium better tailored to their own experience rather than to the experience of their group. The employers would rightfully argue that given their large size and by virtue of the law of large numbers their experience is fairly stable in time, thus allowing the insurer to compute more accurate and fair pure premiums.

Mowbray [6] defines a dependable pure premium to be “one for which the probability is high that it does not differ from the [true] pure premium by more than an arbitrary limit”. Translated in modern mathematical terms, this is essentially asking that

$$\Pr[(1 - k)E[S] \leq S \leq (1 + k)E[S]] \geq p \quad (1)$$

for a small value of k and a large probability p . Here, the random variable S represents the experience of a policyholder, in one form or another. We detail three typical examples below.

1. Mowbray defined S as the number of accidents of an employer, assuming a binomial distribution with parameters n , the number of employees, and θ , the known probability of accident. Solving equation (1) for n , using the central limit theorem yields

$$n \geq \left(\frac{\zeta_{(1-p)/2}}{k} \right)^2 \frac{1 - \theta}{\theta} \quad (2)$$

where ζ_α is the $100(1 - \alpha)$ th percentile of the standard normal distribution.

2. The size of a policyholder may be defined as the expected number of claims in a given period (typically, 1 year). For such cases, one usually defines S as the total amount of claims in the period and further assumes that the distribution of S is a compound Poisson. Solving equation (1) for the Poisson parameter λ yields

$$\lambda \geq \left(\frac{\zeta_{(1-p)/2}}{k} \right)^2 \left(1 + \frac{\text{var}[X]}{E[X]^2} \right) \quad (3)$$

where X is the random variable of claim amounts.

3. The two examples above determine a policyholder’s admissibility to full credibility one period at a time. An alternative criterion is the number of periods of experience. This requires to set S in equation (1) as the average total amount of claims after n years:

$$S = \frac{S_1 + S_2 + \cdots + S_n}{n} \quad (4)$$

where $S_1, \dots, S_n$ are independent and identically distributed random variables of the total amount of claims per period. Then the experience of a policyholder is considered fully credible after

$$n \geq \left(\frac{\zeta_{(1-p)/2}}{k} \right)^2 \frac{\text{var}[S_i]}{E[S_i]^2} \quad (5)$$

periods of experience.

The interested reader will find more examples in [7].

A policyholder’s experience is thus considered fully credible if it fluctuates moderately from one period to another. That is, the credibility criterion is stability. This stability of the experience usually increases with the volume of the policyholder, whether it is expressed in premium volume, number

of claims, number of employees, number of years of experience, or any other exposition base.

Truly appropriate applications of Mowbray's procedure are rare. In insurance, it should be reserved for applications where the stability of the experience is of foremost importance. One good example is the determination of an admissibility threshold to a retrospective insurance system, where the policyholder's premium is readjusted at the end of the year after the total claim amount is known.

To this day, limited fluctuations remains the credibility procedure most widely used by American actuaries. It has been extended in various and often *ad hoc* ways. One such extension deals with the case of a policyholder only partially reaching the full credibility criterion. As proposed originally by Whitney in his seminal paper of 1918 [8], one charges a pure premium π that is a weighted average of the individual experience S and the collective premium m :

$$\pi = zS + (1 - z)m \quad (6)$$

Here, $0 \leq z \leq 1$ is the so-called credibility factor.

Over the years, many partial credibility formulas have been proposed. Among the most widely used are the following:

$$z = \min \left\{ \sqrt{\frac{n}{n_0}}, 1 \right\} \quad (7)$$

$$z = \min \left\{ \left(\frac{n}{n_0} \right)^{2/3}, 1 \right\} \quad (8)$$

and

$$z = \frac{n}{n + K} \quad (9)$$

where n_0 is the full credibility level and K is a constant determined upon judgment, usually to limit the size of the premium change from one year to the next. The third formula is the one introduced by Whitney and the only one in which the (partial) credibility level never reaches unity.

It should be emphasized that in such a context, partial credibility does not seek to find the most accurate premium for a policyholder. The goal is rather to incorporate in the premium as much individual experience as possible while still keeping the premium sufficiently stable. When credibility is used to find the

best estimate of a policyholder's pure risk premium, one should turn toward greatest accuracy methods.

Greatest Accuracy Credibility

The greatest accuracy approach to credibility theory seeks to find the "best" (in a sense yet to be defined) premium to charge a policyholder. This is achieved by distributing the collective premium in an optimal way among the members of a group.

It is now well recognized that the first paper on greatest accuracy credibility was the aforementioned 1918 paper by Whitney [8]. Whitney developed formula (6) out of "the necessity, from the standpoint of equity to the individual risk, of striking a balance between class-experience on the one hand and risk-experience on the other." How this balance is calculated does not depend solely on the stability of the experience, like in the limited fluctuations approach, but rather on the homogeneity of the portfolio. Indeed, Whitney writes:

There would be no experience-rating problem if every risk within the class were typical of the class, for in that case the diversity in the experience would be purely adventitious.

However, Whitney was ahead of his time and his ideas were either not well received or not well understood. For example, he was criticized for using an early version of the Bayes rule; see [9]. For decades, actuaries essentially remembered and used formula (6) and the form $z = n/(n + K)$ for the credibility factor.

The greatest accuracy approach lay dormant until the publication of Arthur L. Bailey's papers [10, 11]. The second paper is an especially enlightening exposition of the state of statistical and actuarial practices at the time. In particular, with respect to credibility theory, Bailey writes:

The trained statistician cries "Absurd! Directly contrary to any of the accepted theories of statistical estimation." The actuaries themselves have to admit that they have gone beyond anything that has been proven mathematically, that all of the values involved are still selected on the basis of judgment, and that the only demonstration they can make is that, in actual practice, it works.

Bailey then poses himself as an advocate of the then controversial Bayesian philosophy (*see Natural*

Resource Management; Risk in Credit Granting and Lending Decisions; Credit Scoring; Reliability Demonstration; Cross-Species Extrapolation), arguing that the notion of prior opinion is natural in actuarial work:

At present, practically all methods of statistical estimation appearing in textbooks on statistical methods or taught in American universities are based on an equivalent to the assumption that any and all collateral information or *a priori* knowledge is worthless. . . . Philosophers have recently discussed the credibilities to be given to various elements of knowledge [12], thus undermining the accepted philosophy of the statisticians. However, it appears to be only in the actuarial field that there has been an organized revolt against discarding all prior knowledge when an estimate is to be made using newly acquired data.

Bailey then shows that the Bayesian estimator of the policyholder's true risk premium obtained by minimizing the mean square error is a credibility premium of the form of equation (6) for certain combinations of distributions. The credibility factor is still of the form $z = n/(n + K)$, where K depends on the parameters of the model.

Modeling Heterogeneity

The classical mathematical model of greatest accuracy credibility was formalized by Bühlmann [1, 5]. Consider a heterogeneous portfolio (group) of I policyholders. The risk level of policyholder $i = 1, \dots, I$ (whether it is a good or a bad driver, for example) is unknown, but past claims data $S_{i1}, \dots, S_{in}$ are available for ratemaking purposes.

We make the following assumptions:

1. Claim amounts of policyholder i are (conditionally) independent and identically distributed with cumulative distribution function (cdf) $F(x|\theta_i)$. Parameter θ_i is the realization of a random variable Θ_i .
2. Random variables $\Theta_1, \dots, \Theta_I$ are identically distributed with cdf $U(\theta)$.
3. The policyholders are independent, meaning that the claims record of one policyholder has no impact on the claims record of another.

The random variable Θ_i represents the risk level of policyholder i . This is an abstract and nonobservable random variable – otherwise, the ratemaking problem

would be easily solved. The portfolio is heterogeneous since each policyholder has its own risk level. Yet, the identical distribution assumption for the random variables $\Theta_1, \dots, \Theta_I$ means that the risk levels all come from the same process. Hence the policyholders are similar enough to justify grouping them in the same portfolio.

In a pure Bayes setting, $U(\theta)$ represents the prior distribution of the risk levels. The distribution is revised – yielding the posterior distribution – as new claims data become available. In the more practical empirical Bayes setting, $U(\theta)$ is rather seen as the structure function of the portfolio, that is the distribution of risk levels within the group of policyholders.

Prediction

The goal in greatest accuracy credibility is to compute the best prediction of the future claims $S_{i,n+1}$ for every policyholder. If the risk level of policyholder i were known, the best (in the mean square sense) prediction would be the expected value

$$\mu(\theta_i) = E[S_{it}|\Theta_i = \theta_i] = \int_0^\infty x dF(x|\theta_i) \quad (10)$$

In the actuarial literature, this function is called the *risk premium* (see **Equity-Linked Life Insurance; Inequalities in Risk Theory; Risk Attitude**). Now, the risk levels and, consequently, the risk premiums are unknown. One is thus left with the equivalent problems of predicting future claims $S_{i,n+1}$ or finding approximations of the risk premiums $\mu(\theta_i)$.

A first approximation of the risk premiums is the weighted average of all possible risk premiums:

$$m = E[\mu(\Theta)] = \int_{-\infty}^\infty \mu(\theta) dU(\theta) \quad (11)$$

This approximation will be the same for all policyholders. It is the *collective premium* (see **Premium Calculation and Insurance Pricing; Ruin Probabilities; Computational Aspects**).

As explained earlier, the collective premium, although globally adequate, fails to achieve an optimal premium distribution among policyholders. In statistical terms, this means that there exist better approximations of the risk premiums when experience is available. Indeed, the best approximation (or

estimation, or prediction) of the risk premium $\mu(\theta_i)$ is the function $g^*(S_{i1}, \dots, S_{in})$ minimizing the mean square error

$$E[(\mu(\Theta) - g(S_{i1}, \dots, S_{in}))^2] \quad (12)$$

where $g(\cdot)$ is any function. Most standard mathematical statistics text (see, e.g. [13]) show that function $g^*(S_{i1}, \dots, S_{in})$ is the so-called Bayesian premium

$$\begin{aligned} B_{i,n+1} &= E[\mu(\Theta)|S_{i1}, \dots, S_{in}] \\ &= \int_{-\infty}^{\infty} \mu(\theta) dU(\theta|S_{i1}, \dots, S_{in}) \end{aligned} \quad (13)$$

Function $U(\theta|x_1, \dots, x_n)$ is the aforementioned posterior distribution of the risk levels, or the revised structure function of the portfolio, after claims experience became available.

Let $f(x|\theta) = F'(x|\theta)$ be the conditional probability density function (pdf) or probability mass function (pmf) of the claim amounts and $u(\theta) = U'(\theta)$ be the pdf or pmf of the risk levels. Then, the posterior distribution of the risk levels is obtained from the prior distribution using the Bayes rule:

$$u(\theta_i|x_1, \dots, x_n) = \frac{f(x_1, \dots, x_n|\theta_i)u(\theta_i)}{\int_{-\infty}^{\infty} f(x_1, \dots, x_n|\theta) dU(\theta)} \quad (14)$$

By conditional independence of claim amounts, this can be rewritten as

$$u(\theta_i|x_1, \dots, x_n) = \frac{\prod_{t=1}^n f(x_t|\theta_i)u(\theta_i)}{\int_{-\infty}^{\infty} \prod_{t=1}^n f(x_t|\theta) dU(\theta)} \quad (15)$$

The Bayesian premium $B_{i,n+1}$ is thus the best computable prediction of the future claims $S_{i,n+1}$. Akin to the collective premium, it is a weighted average of all possible risk premiums, but using the posterior rather than the prior distribution of the risk levels as weighting function. Reversing the argument, one can also see the collective premium as the Bayesian premium of the first year, when no experience is available.

Example 2 Consider policyholder 1 of the simplified portfolio of Example 1. This policyholder can incur at most one claim of amount 1 per period, but with unknown probability. If S_t is the random variable of the experience in year $t = 1, \dots, n$, then $S_t|\Theta = \theta$ has a Bernoulli distribution with parameter θ . Parameter θ is seen as an outcome of a random variable Θ having a beta prior distribution with parameters α and β . That is, we have

$$f(x_t|\theta) = \theta^x (1 - \theta)^{1-x}, \quad x = 0, 1 \quad (16)$$

and

$$u(\theta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \theta^{\alpha-1} (1 - \theta)^{\beta-1}, \quad 0 < \theta < 1 \quad (17)$$

The risk premium, or average claim amount, is $\mu(\theta) = E[S_t|\Theta = \theta] = \theta$. This information is of no real use since the true value of θ is unknown. One can however estimate the average claim amount by the collective premium

$$m = E[\mu(\Theta)] = E[\Theta] = \frac{\alpha}{\alpha + \beta} \quad (18)$$

This is the best approximation in the first year, when no other information is available. However, the results of Table 1 show that the collective premium is inappropriate for this policyholder.

The accumulation of experience allows one to better assess the true value of θ by means of equation (15). The posterior distribution of Θ after n years of experience is, up to a proportionality constant,

$$\begin{aligned} u(\theta|x_1, \dots, x_n) &\propto \theta^{\alpha-1} (1 - \theta)^{\beta-1} \\ &\times \prod_{t=1}^n \theta^{x_t} (1 - \theta)^{1-x_t} \\ &= \theta^{\alpha + \sum_{t=1}^n x_t - 1} (1 - \theta)^{\beta + n - \sum_{t=1}^n x_t - 1} \end{aligned} \quad (19)$$

That is, the distribution of $\Theta|S_1 = x_1, \dots, S_n = x_n$ is a beta distribution with updated parameters $\tilde{\alpha} = \alpha + \sum_{t=1}^n x_t$ and $\tilde{\beta} = \beta + n - \sum_{t=1}^n x_t$. Therefore, the Bayesian premium for year $n + 1$ is

$$B_{n+1} = E[\mu(\Theta)|S_1, \dots, S_n] \quad (21)$$

$$= E[\Theta | S_1, \dots, S_n] \quad (22)$$

$$= \frac{\tilde{\alpha}}{\tilde{\alpha} + \tilde{\beta}} \quad (23)$$

$$= \frac{\alpha + \sum_{t=1}^n S_t}{\alpha + \beta + n} \quad (24)$$

Setting $\alpha = 1$ and $\beta = 4$ in the above results gives a collective premium of 0.2, as in Example 1. Figure 1 shows the evolution of the probability of claim distribution from the prior to the posterior after 10 years of experience. One sees that the distribution gets increasingly concentrated around the true value of θ . Accordingly, the Bayesian premiums in Table 2 are getting closer to the true risk level of the policyholder.

Table 2 Bayesian premiums for policyholder 1 of Table 1 using a beta prior distribution with $\alpha = 1$ and $\beta = 4$

n	x_n	$\sum_{t=1}^n x_t$	$\alpha + \sum_{t=1}^n x_t$	$\beta + n - \sum_{t=1}^n x_t$	B_{n+1}
0	—	—	1	4	0.200
1	0	0	1	5	0.167

10	1	6	7	8	0.467

Figure 1 Posterior distributions for policyholder 1 of Table 1 using a beta prior distribution with $\alpha = 1$ and $\beta = 4$

Linear Bayes Credibility

The Bayesian premium equation (24) can be rewritten as

$$B_{n+1} = \frac{n}{n + \alpha + \beta} \bar{S} + \frac{\alpha + \beta}{n + \alpha + \beta} \frac{\alpha}{\alpha + \beta} \quad (25)$$

$$= z\bar{S} + (1 - z)m \quad (26)$$

with $z = n/(n + \alpha + \beta)$, the same form as equation (6). A premium of this form is called a *credibility premium* and z is the *credibility factor*.

Whitney [8] and Bailey [11] were the first to show that the Bayesian premium is a credibility premium for certain combinations of distributions and, furthermore, that the credibility factor is always of the form $z = n/(n + K)$, with K some constant. Bailey's partial results were extended by Mayerson [14] and later unified by Jewell [15].

The five main combinations of distributions giving a linear Bayesian premium are given in Table 3 (see [3] for a more complete table). Note that in all cases the posterior distribution of the risk parameter is of the same form as the prior, but with revised parameters.

The credibility premium is a weighted average between the collective premium and the individual average of a policyholder. The weight given to the latter increases with the number of years of experience (n). This is both simple and intuitively sound, two desirable properties of the credibility premium.

The Bühlmann and Bühlmann–Straub Models

In practice, the Bayesian premium equation (13) is of limited interest for two main reasons. First, one has to make assumptions on the distributions of $S_{it}|\Theta_i$ and Θ_i , something that can be difficult and highly subjective. Second, the Bayesian premium can be complicated to obtain – see [2] for what happens when the beta distribution in Example 2 is replaced by an apparently simple uniform distribution on (a, b) – and does not in general lie between the individual and collective premiums.

Bühlmann [5] proposed to restrict the approximation of the risk premium to linear functions of the observations. The optimal linear prediction happens to be a credibility premium

$$\pi_{i,n+1}^B = z\bar{S}_i + (1 - z)m \quad (27)$$

with

$$z = \frac{n}{n + s^2/a} \quad (28)$$

$$s^2 = E[\sigma^2(\Theta)] \quad (29)$$

$$a = \text{var}[\mu(\Theta)] \quad (30)$$

and $\sigma^2(\Theta_i) = \text{var}[S_{it}|\Theta_i]$.

The so-called structure parameters m , s^2 and a define the inner structure of the portfolio:

1. m measures the global average of the portfolio;
2. s^2 measures the variability within policyholders, that is of claims in time;

Table 3 Combinations of distributions yielding a linear Bayesian premium and main results

$f(x \theta)$	$u(\theta)$	B_{n+1}	z
Bernoulli(θ)	Beta(α, β)	$\frac{\alpha + \sum_{t=1}^n S_t}{\alpha + \beta + n}$	$\frac{n}{n + \alpha + \beta}$
Geometric(θ)	Beta(α, β)	$\frac{\beta + \sum_{t=1}^n S_t}{\alpha + n - 1}$	$\frac{n}{n + \alpha - 1}$
Poisson(θ)	Gamma(α, λ)	$\frac{\alpha + \sum_{t=1}^n S_t}{\lambda + n}$	$\frac{n}{n + \lambda}$
Exponential(θ)	Gamma(α, λ)	$\frac{\lambda + \sum_{t=1}^n S_t}{\alpha + n - 1}$	$\frac{n}{n + \alpha - 1}$
Normal(θ, σ_2^2)	Normal(μ, σ_1^2)	$\frac{\sigma_1^2 \sum_{t=1}^n S_t + \sigma_2^2 \mu}{n\sigma_1^2 + \sigma_2^2}$	$\frac{n}{n + \sigma_2^2/\sigma_1^2}$

3. a measures the variability between policyholders, that is the heterogeneity of the portfolio.

One can see that more weight will be given to individual experience in the following scenarios:

1. the number of periods of experience (n) is large. This is justified since the experience of a policyholder represents its true risk level in the long run;
2. the value of parameter s^2 is small, the claims experience is globally stable in time. The individual averages $\bar{S}_i$ are thereby indicative of the risk levels, hence reducing the need for the collective premium;
3. the value of a is large, the portfolio is heterogeneous. Therefore, the individual averages are more accurate approximations of the risk premiums than the collective premium.

Figures 2 and 3 provide a graphical interpretation of the last two points. Each curve in these figures represents the experience of one policyholder. In each case, the credibility factor is largest in the figures marked (b).

The Bühlmann–Straub model (*see Insurance Pricing/Nonlife*) [16] is a generalization of the Bühlmann model allowing for variable exposure. This is essential in lines of business in which the size of the policyholders can vary within a portfolio. Consider for example workers compensation insurance where

policyholders are employers: the exposure to risk of an employer with 1000 employees is much larger than that of an employer with only 10 employees.

In the Bühlmann–Straub model, a weight w_{it} (the number of employees or the payroll, for example) is assigned to each observation that we will now denote by X_{it} . One would expect that the experience of the larger policyholder will be more stable in time. To reflect this, the assumption of identical distribution used in Bühlmann’s model is relaxed to let the conditional variance of an observation be inversely proportional to its weight:

$$\text{var}[X_{it}|\Theta_i = \theta_i] = \frac{\sigma^2(\theta_i)}{w_{it}} \quad (31)$$

For this relation to hold, the observations X_{it} must now be ratios. Typically, the data will be defined as claim amounts divided by the exposure base:

$$X_{it} = \frac{S_{it}}{w_{it}} \quad (32)$$

The credibility premium differs from equation (27) in two respects only: the individual premium is estimated by a weighted average, and the credibility factor is a function of the total weight of a policyholder. We have

$$\pi_{i,n+1}^{\text{BS}} = z_i X_{iw} + (1 - z_i)m \quad (33)$$

Figure 2 Effect of $s^2 = E[\sigma^2(\Theta)]$ on the credibility factor. (a) Large s^2 , experience is too volatile to be reliable. (b) Small s^2 , individual averages are more reliable. Means are the same in (a) and (b)

Figure 3 Effect of $a = \text{var}[\mu(\Theta)]$ on the credibility factor. (a) Small a , the portfolio is homogeneous. (b) Large a , the portfolio is heterogeneous. Variances are the same in (a) and (b)

with

$$z_i = \frac{w_{i\Sigma}}{w_{i\Sigma} + s^2/a} \quad (34)$$

$$X_{iw} = \sum_{t=1}^n \frac{w_{it}}{w_{i\Sigma}} X_{it} \quad (35)$$

and $w_{i\Sigma} = \sum_{t=1}^n w_{it}$. Parameters s^2 and a are defined as in equations (29) and (30), respectively.

In practice, the unknown structure parameters m , s^2 , and a are estimated from the available data; see [17, 18] or [3] for discussions on this topic. (Function `cm` of the R package `actuar` [19] implements all credibility calculations.)

Example 3 The Bühlmann model is appropriate to estimate the pure premiums (or probability of accident) for year 11 in Example 1. Unbiased estimators of the structure parameters are

$$\hat{m} = \bar{S} = 0.23 \quad (36)$$

$$\hat{s}^2 = \frac{1}{I(n-1)} \sum_{i=1}^I \sum_{t=1}^n (S_{it} - \bar{S}_i)^2 = 0.1367 \quad (37)$$

$$\hat{a} = \frac{1}{I-1} \sum_{i=1}^I (\bar{S}_i - \bar{S})^2 - \frac{\hat{s}^2}{n} = 0.0464 \quad (38)$$

Replacing these values in equation (27) yields the estimated credibility premiums of Table 4. One will

note that the premium for policyholder 1 obtained with this non parametric approach is different from the pure Bayes premium of Example 2.

Other Credibility Models

Random Coefficients Regression Model

Consider a data set in which a structural linear upward trend is present. Since the Bühlmann and Bühlmann–Straub models assume that the risk premium remains constant in time, these models will

Table 4 Bühlmann credibility premiums for the data of Table 1

Policy holder	Individual premium ($\bar{S}_i$)	Credibility factor ($\hat{z}$)	Credibility premium ($\hat{\pi}_{i,11}$)
1	0.6	0.772	0.516
2	0.3	0.772	0.284
3	0.2	0.772	0.207
4	0.2	0.772	0.207
5	0.2	0.772	0.207
6	0.1	0.772	0.130
7	0.0	0.772	0.052
8	0.0	0.772	0.052
9	0.7	0.772	0.593
10	0.0	0.772	0.052

systematically underestimate future claims. The random coefficients regression credibility model introduced by Hachemeister [20] remedies this situation by relaxing the constant mean assumption of the Bühlmann–Straub model in favor of

$$E[X_{it}|\Theta_i = \theta_i] = \beta_0(\theta_i) + \beta_1(\theta_i)t \quad (39)$$

Therefore, one has to estimate the intercept and slope of a regression line for each policyholder, but these depend on the unknown risk levels of the policyholders. The optimal estimation of the slope for one policyholder is a credibility weighted average between the estimation using this policyholder's experience only and the estimation using all the portfolio data. The same idea holds for the intercept.

The formulas in this model make heavy use of matrix notation and quickly become cumbersome. We refer the interested reader to [18] for an up-to-date discussion on this topic.

Of course, one can use something other than a linear trend model. In general, one would have

$$E[\mathbf{X}_i|\Theta_i = \theta_i] = \mathbf{Y}\boldsymbol{\beta}(\theta_i) \quad (40)$$

where $\mathbf{X}_i = (X_{i1}, \dots, X_{in})'$, $\mathbf{Y}$ is an $n \times (p+1)$ design matrix and $\boldsymbol{\beta}(\theta_i) = (\beta_0(\theta_i), \dots, \beta_p(\theta_i))'$ is a vector of random coefficients.

Hierarchical Credibility

It is common that the group of policyholders that we have been referring to as *the portfolio* is actually just a fraction of a much larger classification scheme. Consider, for example, a hierarchical (or treelike) structure in which policyholders are classified first in “sectors”, and then in “classes”. Applying a credibility model within one class will not make use of collateral data from other classes of the same sector, even though this data can be useful to assess the true risk level of the class and, ultimately, of the policyholders (*see Dependent Insurance Risks*).

Exploiting collateral data was the main rationale brought forth by Jewell [21] to introduce the hierarchical credibility model. The credibility premium of a policyholder remains of the same form as equation (27) or equation (33), but with the complement of credibility $(1 - z_i)$ given to the *credibility premium* of the class. The latter is, in turn, a weighted average between the experience of the class and the credibility premium of the sector, and so on, until the top level is reached.

Complete formulas for the hierarchical credibility model can be found in [3, 18, 22, 23]. Hierarchical credibility is particularly well suited for a geometrical interpretation; see [24]. Moreover, [3] has a discussion on the uses and misuses of hierarchical models.

Crossed Classification Credibility

Consider an automobile insurance portfolio in which policyholders are classified according to gender and age. Intuitively, young women share risk characteristics with young men, who themselves share risk characteristics with older men. A hierarchical classification structure is inappropriate for such a portfolio since the risk factors are not nested, but rather crossed.

Dannenburg [25] adapted the crossed classification random-effects models, well known in statistical modeling, to the credibility theory context. This results in a very general model encompassing the Bühlmann and Bühlmann–Straub models and, to some extent, the hierarchical model; see [3, 26] for details and formulas.

Concluding Remarks

Credibility theory is related – without being identical – to various forecasting techniques in statistics. There has been a trend over the last decade or so to increasingly draw links between credibility and techniques such as the Kalman filter (*see Non-life Loss Reserving*) [27], longitudinal models [28], variance components models [26], or generalized linear models [29]. See also [30] for further comments and references.

A lot of research in credibility theory has been and will likely continue to be devoted to estimation of the structure parameters. Robust estimation or generalized estimating equations come to mind as procedures making their way into credibility. Moreover, the tidal wave of dependence modeling that has swept risk theory around the start of the new millennium has just started to touch credibility theory [31]. More is expected in the near future.

VINCENT GOULET

Credit Migration Matrices

Credit migration (*see* **Default Risk**) or transition matrices (*see* **Group Decision**), which characterize past changes in credit quality of obligors (typically firms), are cardinal inputs to many risk management applications, including portfolio risk assessment (*see* **Credit Scoring via Altman Z-Score; Volatility Modeling**), pricing of bonds and credit derivatives (*see* **Insurance Pricing/Nonlife; Default Risk; Mathematical Models of Credit Risk**), and assessment of risk capital. For example, standard bond pricing models such as in [1] require a ratings projection of the bond to be priced. These matrices even play a role in regulation: in the New Basel Capital Accord (*see* **Enterprise Risk Management (ERM); Credit Risk Models; Solvency; Extreme Value Theory in Finance**) [2], capital requirements are driven in part by ratings migration. This article provides a brief overview of credit migration matrix basics: how to compute them, how to make inference and compare them, and some examples of their use. We pay special attention to the last column of the matrix, namely, the migration to default. Along the way, we illustrate some of the points with data from one of the rating agencies, Standard & Poor's (S&P).

To fix ideas, suppose that there are k credit ratings for $k - 1$ nondefault states and one default state. This rating is designed to serve as a summary statistic of the credit quality of a borrower or obligor such as a firm. Ratings can be either public as provided by one of the rating agencies (*see* **Nonlife Insurance Markets; Informational Value of Corporate Issuer Credit Ratings; Credit Scoring via Altman Z-Score**) such as Fitch, Moody's, or S&P, or they can be private such as an obligor rating internal to a bank. For firms that have issued public bonds, typically at least one rating from a rating agency is available [3]. As such, the rating agencies are expected to follow the credit quality of the firm. When that changes, the agency may decide to upgrade or downgrade the credit rating of the firm. In principle, the process from initial rating to the updates is the same within a financial institution when assigning so-called internal ratings, though the monitoring may be less intensive and hence the updating may be less frequent [4]. Purely as a matter of convenience, we follow the notation used by Fitch and S&P which, from best

to worst, is AAA, AA, A, BBB, BB, B, CCC, and of course, D; so $k = 8$.

All three rating agencies actually provide rating modifiers (e.g., for Fitch and S&P, these are $\pm$, as in AA- or AA+) to arrive at a more nuanced, 17+ state rating system. But for simplicity, most of the discussion in this article is confined to whole grades.

A concrete example of a credit migration is given below in Table 1 in which we show the 1-year migration probabilities for firms, estimated using S&P ratings histories from 1981 to 2003. A given row denotes the probability of migrating from rating i at time T to any other rating j at time $T + 1$. For example, the 1-year probability that an AA rated firm is downgraded to A is 7.81%.

Several features – and these are typical – immediately stand out. First, the matrix is diagonally dominant, meaning that large values lie on the diagonal (made bold for emphasis) denoting the probability of no change or migration: for most firms ratings do not change. Such stability is by design [5]: the agencies view that investors look to them for just such stable credit rating assessments. The next largest entries are one step off the diagonal, meaning that when there are changes, they tend to be small, that is, one or perhaps two rating grades.

The final column, the migration to default, deserves special attention. Probabilities of default increase roughly exponentially as one descends the credit spectrum from best (AAA) to worst (CCC). Note that in our sample period of 1981–2003, no AAA-rated firm defaulted, so that the empirical estimate of this probability of default (PD) (PD_{AAA}) is zero. But is zero an acceptable estimate of PD_{AAA} ? We revisit this question below.

To square the matrix, the last row is the unit vector that simply states that default is an absorbing state: once a firm is in default, it stays there. By implication, it means that all firms eventually default, though it may take a (very) long time. A firm that emerges from bankruptcy (default) is typically treated as a new firm.

Estimation

Several approaches to estimating these migration matrices are presented and reviewed in [6] and compared extensively in [7]. Broadly there are two approaches, cohort and two variants of duration

Table 1 One-year credit migration matrix using S&P rating histories, 1981–2003. Estimation method is cohort. All values in percentage points

		T + 1							
		AAA	AA	A	BBB	BB	B	CCC	D
T	AAA	92.29	6.96	0.54	0.14	0.06	0.00	0.00	0.000
	AA	0.64	90.75	7.81	0.61	0.07	0.09	0.02	0.010
	A	0.05	2.09	91.38	5.77	0.45	0.17	0.03	0.051
	BBB	0.03	0.20	4.23	89.33	4.74	0.86	0.23	0.376
	BB	0.03	0.08	0.39	5.68	83.10	8.12	1.14	1.464
	B	0.00	0.08	0.26	0.36	5.44	82.33	4.87	6.663
	CCC	0.10	0.00	0.29	0.57	1.52	10.84	52.66	34.030
	D	0.00	0.00	0.00	0.00	0.00	0.00	0.00	100

(or hazard)–parametric (imposing time homogeneity) and nonparametric (relaxing time homogeneity). The assumption of time homogeneity essentially implies that the process is time invariant: the analyst can be indifferent between two equally long samples drawn from different time periods.

The straight forward cohort approach has become the industry standard. In simple terms, the cohort approach just takes the observed proportions from the beginning of the year to the end (for the case of annual migration matrices) as estimates of migration probabilities (*see Default Risk*). Suppose there are $N_i(t)$ firms in rating category i at the beginning of the year t , and $N_{ij}(t)$ migrated to grade j by year end. An estimate of the transition probability for year t is $P_{ij}(t) = \frac{N_{ij}(t)}{N_i(t)}$. For example, if two firms out of 100 migrated from grade “AA” to “A”, then $P_{AA \rightarrow A} = 2\%$. Any movements within the year are not accounted for. Typically, firms whose ratings were withdrawn or migrated to not rated (NR) status are removed from the sample. This approach effectively treats migrations to NR as being noninformative [8]. It is straightforward to extend this approach to multiple years. For instance, suppose that we have data for T years, then the estimate for all T years is:

$$P_{ij} = \frac{N_{ij}}{N_i} = \frac{\sum_{t=1}^T N_{ij}(t)}{\sum_{t=1}^T N_i(t)} \quad (1)$$

Indeed, this is the maximum likelihood estimate of the transition probability under a discrete time-homogeneous Markov chain. The matrix shown in Table 1 was estimated using the cohort approach.

Any rating change activity that occurs *within* the period is ignored, unfortunately. A strength of the alternative duration approach is that it counts *all* rating changes over the course of the year (or multiyear period) and divides by the number of firm-years spent in each state or rating to obtain a matrix of migration intensities that are assumed to be time homogenous. Under the assumption that migrations follow a Markov process, these intensities can be transformed to yield a matrix of migration probabilities.

Following [6], the $k \times k$ transition probability matrix $\mathbf{P}(t)$ can be written as

$$\mathbf{P}(t) = \exp(\mathbf{\Gamma}t) \quad t \geq 0 \quad (2)$$

where the exponential is a matrix exponential, and the entries of the generator matrix $\mathbf{\Gamma}$ satisfy

$$\begin{aligned} \gamma_{ij} &\geq 0 \text{ for } i \neq j \\ \gamma_{ii} &= - \sum_{j \neq i} \gamma_{ij} \end{aligned} \quad (3)$$

The second expression in equation (3) merely states that the diagonal elements are such to ensure that the rows sum to zero.

The maximum likelihood estimate of an entry γ_{ij} in the intensity matrix $\mathbf{\Gamma}$ is given by

$$\hat{\gamma}_{ij} = \frac{n_{ij}(T)}{\int_0^T Y_i(s) ds} \quad (4)$$

where $Y_i(s)$ is the number of firms with rating i at time s , and $n_{ij}(T)$ is the total number of transitions over the period from i to j where $i \neq j$. The denominator in equation (4) effectively is the number of “firm-years” spent in state i . Thus for a horizon

the additional year of data has only a modest impact on the estimate of the migration matrix.

One may be particularly interested in the precision of default probability estimates. The first to report confidence sets for default probability estimates were Christensen *et al.* [13], who used a parametric bootstrap. An interesting approach for the common case where no defaults have actually been observed was developed in [17] on the basis of the most prudent estimation principle, assuming that the ordinal borrower ranking is correct (i.e., monotonic). A systematic comparison of confidence intervals was provided by Hanson and Schuermann [18], using several analytical approaches, as well as finite-sample confidence intervals obtained from parametric and nonparametric bootstrapping. They find that the bootstrapped (*see Benchmark Dose Estimation; Combining Information; Nonlife Loss Reserving*) intervals for the duration-based estimates are surprisingly tight and that the less efficient cohort approach generates much wider intervals. Yet, even with the tighter bootstrapped confidence intervals for the duration-based estimates, it is impossible to statistically distinguish notch-level (grade with $\pm$ modifiers) PD s for neighboring investment grade ratings, e.g., a PD_{AA-} from a PD_{A+} or even a PD_A . However, once the speculative grade barrier (i.e., moving from $BBB-$ to $BB+$) is crossed, they are able to distinguish quite cleanly notch-level estimated default probabilities. Moreover, both [18, 19] show that PD point estimates and, unsurprisingly, their confidence intervals vary substantially over time.

An advantage of the duration over the cohort estimation approach is that it delivers nonzero default probability estimates even when no actual defaults were observed. As a result, the PD estimates can be quite different, even taking into account the issue of estimation noise raised above. This is shown in Table 3 at the more granular notch-level using S&P ratings histories for 1981–2004. Note that neither method produces monotonically increasing PD s, though in the presence of estimation noise, this nonmonotonicity need not be surprising. Put differently, even if the true but unknown PD s are monotonically increasing, because each rating's PD is estimated with error, the *estimates* need not be monotonic. Since no actual defaults have been observed for AAA-rated (nor AA+ or AA rated) firms over the course of the sample period, the cohort estimates must be identically equal to zero even as the duration

Table 3 Unconditional probability of default (PD) estimates compared using S&P rating histories, 1981–2004. All values are in basis points (bp), where 100 bp = 1%

	Cohort	Duration
AAA	0.00	0.02
AA+	0.00	0.05
AA	0.00	0.65
AA–	2.43	0.26
A+	5.42	0.31
A	4.00	0.88
A–	3.97	0.68
BBB+	22.99	3.22
BBB	30.42	8.48
BBB–	41.76	12.03
BB+	57.24	20.61
BB	104.63	41.41
BB–	197.34	84.32
B+	336.84	172.33
B	942.53	707.07
B–	1384.62	1247.41
CCC	3253.55	4320.35

(*see Asset–Liability Management for Life Insurers; Securitization/Life*) approach generates a very small, but nonzero, estimate of 0.02 basis points (bp) (or 0.0002%).

In looking at the difference for PD_{CCC} between the two methods, Lando and Skodeberg [6] observe that most firms default after only a brief stop in the CCC rating state. By contrast, the intermediate grades generate duration PD estimates that are below the cohort estimates. As argued in [18], if ratings exhibit downward persistence (firms that enter a state through a downgrade are more likely to be downgraded than other firms in the state), as shown among others in [6, 11, 12], one would expect PD s from the duration-based approach, which assumes that the migration process is Markov, to be downward biased. Such a bias would arise because the duration estimator ignores downward ratings momentum and consequently underestimates the probability of a chain of successive downgrades ending in default.

The New Basel Accord sets a lower bound of 0.03% on the PD estimate that may be used to compute regulatory capital for the internal ratings based (IRB) approach [2, §285]. Table 3 suggests that the

top two ratings, AAA and AA, would both fall under that limit and would thus be indistinguishable from a regulatory capital perspective. Indeed Hanson and Schuermann [18] report that once 95% confidence intervals are taken into account, the top three ratings, AAA through A, are indistinguishable from 0.03%.

Applications

The applications and uses of credit migration matrices are myriad, from asset pricing to portfolio choice, and risk management to bank regulation. Two examples are presented here; the pricing of a yield spread option and the computation of risk capital for a credit portfolio using CreditMetrics.

Yield Spread Option

A yield spread option enables the buyer and seller to speculate on the evolution of the yield spread. The yield spread is defined as the difference between the continuously compounded yield of a risky and a riskless zero-coupon bond with the same maturity. Depending on the option specifications, the relevant spread is either an individual forward spread in case of European options, or a bundle of forward spreads in case of American options. Call (put) option buyers expect a decreasing (increasing) credit spread.

Yield spread options are priced using Markov chain models such as the one presented in [20]. To price such an option, the following are needed: the yield curve of default-free zero-coupon bonds, the term structure of forward credit spreads, both the option and yield spread maturity (of the underlying bond), an estimate of the recovery rate in the event of default, the current rating of the bond, and of course the migration vector of the same maturity as the option corresponding to that rating. This is illustrated in Figure 1 below, for a yield spread option on a BBB-rated bond.

Risk Capital for a Credit Portfolio

The purpose of capital is to provide a cushion against losses for a financial institution. The amount of required economic capital is commensurate with the risk appetite of the financial institution. This boils down to choosing a confidence level in the loss (or value change) distribution of the institution

Figure 1 Illustration of a yield spread option on a BBB-rated bond

with which senior management is comfortable. For instance, if the bank wishes to have an annual survival probability of 99%, this will require less capital than a survival probability of 99.9%, where the latter is the confidence level to which the New Basel Capital Accord is calibrated [2], and is typical for a regional bank (commensurate with a rating of about A-/BBB+, judging from Table 3). The loss (or value change) distribution is arrived at through internal credit portfolio models.

One such credit portfolio model (*see Credit Risk Models; Credit Value at Risk*) is CreditMetrics [21], a portfolio application of the options-based model of firm default due to Merton [22]. Given the credit rating distribution of exposures today, and inputs similar to the pricing of the yield spread option discussed in the section titled “Yield Spread Option”, namely, the yield curve of default-free zero-coupon bonds, the term structure of forward credit spreads, an estimate of the recovery rate in the event of default for each rating, and of course the credit migration matrix, the model generates a value distribution of the credit portfolio through stochastic simulation. An illustration is given in Figure 2 above. For instance, the 99% value at risk (VaR) (*see Credit Scoring via Altman Z-Score; Risk Measures and Economic Capital for (Re)insurers; Default Risk*) is -14.24%, and the 99.9% VaR is -19.03%. Thus only for 1 year out of 1000 would the portfolio manager expect his or her portfolio to lose more than 19.03% of its value.

Figure 2 Illustrative example of a credit portfolio value change distribution using CreditMetrics

Summary

This article provided a brief overview of credit migration or transition matrices, which characterize past changes in credit quality of obligors (typically firms). They are cardinal inputs to many risk management applications, including portfolio risk assessment, the pricing of bonds and credit derivatives, and the assessment of regulatory capital as is the case for the New Basel Capital Accord. We addressed the question of how to estimate these matrices, how to make inference and compare them, and provided two examples of their use: the pricing of a derivative called a yield spread option, and the calculation of the value distribution for a portfolio of credit assets. The latter is especially useful for risk management of credit portfolios.

Credit Risk Models

The computation of the distribution of aggregate losses in credit portfolios has become especially important for risk management (*see Asset–Liability Management for Life Insurers; Multistate Models for Life Insurance Mathematics; Mathematics of Risk and Reliability: A Select History*) and securitization (*see Securitization/Life*) purposes. Banks and financial institutions need to assess the risks within their credit portfolios both for regulatory requirements and for internal risk management: for instance, they may compute risk measures such as the value at risk or the expected shortfall associated with their credit risk exposure. Credit risk has been transferred from banks to other investors such as insurance companies or hedge funds that act with respect to commercial banks as reinsurance companies act with respect to insurance firms. This securitization process involves some “tranching” of credit risk similar to stop-loss reinsurance. Specific products such as credit default swaps and single tranche collateralized debt obligations (CDOs) (*see Tavakoli [1] for a description of the CDO market*) have been designed for such risk transfer. The computation of the CDO tranche premiums also involves the aggregate credit loss distributions over different time horizons. The purpose of this article is to describe the most commonly used approach to compute such loss distributions. Before this, we briefly review the risks involved in a credit portfolio.

An Overview of Risks Involved

Default Risk. Default risk is related to the inability of a borrower to reimburse a loan or a bond. More precisely, one can think of different credit events such as the following:

- the failure to meet payment obligations when due;
- bankruptcy (for nonsovereign entities) or Moratorium (for sovereign entities only);
- repudiation;
- material adverse restructuring of debt;
- obligation acceleration or obligation default.

The definition of a credit event hinges on the relevant bankruptcy rules (*see Default Risk*) that themselves depend upon geographical regions, quality of

the borrower, and seniority of the loan. For example, personal bankruptcy could be accessed more easily in the United States than in the United Kingdom. The same comparison also holds for corporates. This will result in differences in frequency and claim severity. Let us additionally remark that as far as retail credit is concerned, the banks need to decide at which stage a loan is actually in default. For instance, a single outstanding payment on a mortgage is not usually considered as a default event. We refer to de Malherbe [2] for a detailed quantitative assessment of the credit default swaps covenants.

Change in Credit Quality: Credit Migrations, Change in Credit Spreads. In addition to default risk, credit migrations are associated with changes in credit quality. For example, in financial markets, even if default-free interest rates remain constant, defaultable bond prices change prior to default. This is also known as *credit spread risk* (*see Extreme Value Theory in Finance*). For example, an increase in default probability (*see Credit Migration Matrices; Default Correlation; Copulas and Other Measures of Dependency*) following a credit rating downgrading, adverse earnings announcements should lead to a drop in the company’s bond prices. This is not specific to corporates; default probabilities for individuals usually increase when the borrower becomes unemployed.

Let us emphasize that credit contracts may have much longer maturities than insurance contracts. For example, in a typical 30-year mortgage, the annuities remain fixed even if the credit quality of the borrower deteriorates; the lender cannot raise payments yearly as in the insurance markets.

Recovery Risk. In case of default, the lender only gets a fraction of the promised payments. In the most severe cases, no further cash flows are being paid by the borrower. In case of bankruptcy, the assets of the defaulted firm are being sold to investors and the proceeds are used to reimburse the lenders. After liquidation, the proceeds may be in excess of the commitments to the lenders, which means that the loss severity can be equal to zero. For simplicity, we will consider that the loss given default (*LGD*) is equal to the difference between the face value of the loan or the bond and the recovered value. As a consequence, *LGD* are bounded.

Dependence Between Defaults. Since common macroeconomic factors, such as business cycles, level of unemployment, and shifts in monetary policy drive default both frequency and credit loss severity, we cannot rely on the standard insurance framework and we need to cope with dependence between default events. Macroeconomic shocks can be considered as exogenous to defaults and usually lead to positive dependence. Dependence can also occur at a local level owing to interactions between firms. For example, default of a bank can be seen as a bad signal with respect to the assets of its competitors in an incomplete information framework. Conversely, default of a firm could raise the market power of competitors, leading to extra profits and an increase in credit quality. As can be seen from these examples, defaults can be informative with respect to the credit quality of survivors; this is known as *contagion effects* or *infectious defaults*.

We will further detail the most commonly used approaches to the dependence between defaults as far as the computation of loss distributions is involved. Dependence usually results in much fatter tails and an increase in senior CDO tranche premiums, which correspond to stop-loss reinsurance premiums in insurance markets.

Computation of Loss Distributions

Marginal Default Probabilities. The individual default probabilities of the obligors within a credit portfolio are a key input in the computation of aggregate loss distributions (see **Premium Calculation and Insurance Pricing; Risk Measures and Economic Capital for (Re)insurers**).

As far as retail portfolios are involved, banks could either use internal data or, if available, public information about defaults and obligors' individual characteristics. Usually, obligors are grouped in homogeneous clusters and thus marginal default probabilities depend upon static observables, such as age, marital status, and so on. Credit scoring techniques based upon logistic regression or classification techniques are routinely used. For instance in the United States, FICO scores have almost become a market standard.

When it comes to corporate obligors, the number of obligors is usually much smaller and especially for investment grade bonds. Thus the number of observed

defaults is much smaller, which leads to some statistical difficulties. To assess the magnitude of default probabilities, creditors need to rely on the analysis of financial statements. This can be done at the lender's level, usually within the credit department of lending banks or owing to the rating agencies. While the financial analysis is forward looking and rates obligors along a discrete grid, further data analysis is required to translate credit ratings into default probability as illustrated by Moody's historical default rates (see **Default Risk**) of bond issuers.

Another approach that can be thought of, especially for publicly traded companies, is the use of the stock market. In the structural model of Merton (see **Credit Scoring via Altman Z-Score; Default Correlation**), default occurs if the market value of the company's assets falls below a prespecified threshold. The lower the value of the stock, the smaller the distance to the default barrier and the more likely default will occur. This is the route followed by Kealhofer [3].

Historical and Market Implied Default Probabilities

In frictionless and arbitrage-free financial markets (see **Equity-Linked Life Insurance**), prices of financial securities are computed as the expectation of the discounted risky cash flows. Let us consider a simplified defaultable bond with a single promised cash flow of 1 \$ to be paid at time t . In case of default, we assume that no payment will be made (recovery rate is equal to zero). Let us denote by $\bar{B}$ the market price for such a bond and by r , the (continuously compounded) discount rate for maturity t . $\bar{B} = e^{-rt} Q(\tau > t)$, where τ denotes the default date and $Q(\tau > t)$ is the survival probability. If the previous defaultable discount bond is actually traded, the survival probability can be readily computed as $Q(\tau > t) = \bar{B} \times e^{rt}$. It appears that the default probabilities extracted from bond prices are higher than the default probabilities computed from historical data on defaults. Investors require a risk premium to hold defaultable bonds, reflecting imperfect diversification of default risk: if default events of obligors were independent and the number of obligors very large, default risk could be perfectly diversified owing to the law of large numbers. This is the classical framework in insurance theory and in such a competitive market, the computation of bond prices should

follow the “pure premium actuarial rule”, meaning that default probabilities implied from financial markets should equal the “historical default probabilities”. For high quality names, say AAA bonds, defaults are rare events, the number of traded bonds small, and the dependence between default events is larger than for high yield names since extreme macroeconomic factors drive defaults of such firms. Not surprisingly, the ratio of market implied and historical default probabilities is larger for these high quality names compared with speculative bonds (*see Credit Migration Matrices*).

Credit risk measurement usually involves historical default probabilities, while securitization and risk transfer (typically the pricing of CDO tranches) requires the use of market implied probabilities. We will denote by $F_1, \dots, F_n$ the marginal distribution functions associated with the names in the credit portfolio, that can be either historical or market implied depending on the context.

Individual and Collective Models. Let us denote by $\tau_1, \dots, \tau_n$ the default dates of n obligors, by $N_1(t) = 1_{\{\tau_1 \leq t\}}, \dots, N_n(t) = 1_{\{\tau_n \leq t\}}$ the corresponding default indicators for some given time horizon t and by LGD_i the LGD on name i . We assume that the maximum loss is normalized to unity, the aggregate loss on the credit portfolio for time horizon t is then given by:

$$L(t) = \frac{1}{n} \sum_{i=1}^n LGD_i \times N_i(t) \quad (1)$$

Let us remark that we only cope with defaults (or “realized losses”) and not losses due to changes in credit quality of nondefaulted bonds. As can be seen from equation (1), the standard credit risk model is an individual model.

Structural Models and Gaussian Copulas

Inspired by the structural approach of Merton, defaults occur whenever assets fall below a prespecified threshold (see Gupton *et al.* [4], Finger [5], and Kealhofer [3]). In the multivariate case, dependence between default dates ensues dependence between asset price processes. On the other hand, the most commonly used approach states that default dates are associated with a Gaussian copula (Li [6]) (*see Copulas and Other Measures of Dependency*). Thus,

default indicators follow a multivariate probit model. For simplicity, the Gaussian copula model can be viewed as a one period structural model. Consequently, Hull *et al.* [7] show that from a practical point of view, the copula and structural approaches lead to similar loss distributions. Burtshell *et al.* [8] point out that in many cases, the computation of the loss distribution is rather robust with respect to the choice of copula.

For simplicity, we will assume that LGD_i is non-stochastic. We will thus concentrate upon the modeling of dependence between default dates rather than upon the recovery rates. For large credit portfolios, taking into account stochastic LGD has only a small impact on the loss distribution provided that LGD are independent of default indicators. Altman *et al.* [9] analyze the association between default and recovery rates on corporate bonds over the period 1982–2002; they show negative dependence, i.e., defaults are more severe and frequent during recession periods. An analysis of the changes in the loss distributions due to recovery rates possibly correlated with default dates is provided in Frye [10] or in Chabaane *et al.* [11]; this usually results in fatter tails of the loss distributions.

The assumption that default indicators are independent given a low dimensional factor is another key ingredient in credit risk models (see Wilson [12, 13], Gordy [14], Crouhy *et al.* [15], Pykhtin and Dev [16], and Frey and McNeil [17]). This dramatically reduces the numerical complexities when computing loss distributions. While commercial packages usually involve several factors, we will further restrict to the case of a single factor that eases the exposition. This is also the idea behind the regulatory Basel II framework (see Gordy [18]). Thus, in the Gaussian copula (or multivariate probit) (*see Dose–Response Analysis; Potency Estimation; Credit Scoring via Altman Z-Score*) approach, the latent variables associated with default indicators $N_i(t) = 1_{\{\tau_i \leq t\}}, i = 1, \dots, n$ can be written as: $V_i = \rho_i V + \sqrt{1 - \rho_i^2} \bar{V}_i, i = 1, \dots, n$ where $V, \bar{V}_1, \dots, \bar{V}_n$ are independent standard Gaussian variables. The default times are then expressed as: $\tau_i = F_i^{-1}(\Phi(V_i))$ where Φ denotes the Gaussian cdf. In other words default of name i occurs before t if, and only if, $V_i \leq \Phi^{-1}(F_i(t))$. It can be easily checked that default dates are independent given the factor V and that the conditional default probabilities can be written as

$P(\tau_i \leq t|V) = \Phi\left(\frac{\Phi^{-1}(F_i(t) - \rho_i V)}{\sqrt{1 - \rho_i^2}}\right)$, $i = 1, \dots, n$. Let us remark that due to the theory of stochastic orders, increasing any of the correlation parameters $\rho_1, \dots, \rho_n$ leads to an increase in the dependence of the default times $\tau_1, \dots, \tau_n$ with respect to the supermodular order. The corresponding copula of default times is known as the *one-factor Gaussian copula*.

Clearly, determining the correlation parameters is not an easy task especially when the number of names involved in the credit portfolio is large. Extra simplicity consists in grouping names in homogeneous portfolios with respect to sector or geographical region. We refer to Gregory and Laurent [19] for a discussion of this approach. The easier to handle approach consists in assuming some kind of homogeneity at the portfolio level. For instance, we can assume that the correlation parameter is name independent. This is known as the *flat correlation* approach. This both underlies the computations of risk measures in the Basel II agreement framework (see **From Basel II to Solvency II – Risk Management in the Insurance Sector; Credit Migration Matrices**) and of CDO tranche premiums.

Let us also remark that when the marginal default probabilities are equal, i.e., $F_1(t) = \dots = F_n(t)$, then the default indicators $N_1(t), \dots, N_n(t)$ are exchangeable (see **Imprecise Reliability; Bayesian Statistics in Quantitative Risk Assessment**). Conversely, when the default indicators are exchangeable, one can think of using de Finetti's theorem (see **Subjective Probability**), which states the existence of univariate factor such that the default indicators are conditionally independent given that factor. In other words, for “homogeneous portfolios”, the assumption of a one-dimensional factor is not restrictive. The only assumption to be made is upon the distribution of conditional default probabilities. We refer to Burtschell *et al.* [8, 20] for some discussion of different mixing distributions.

Computation of Loss Distributions

Let us now discuss the computation of aggregate loss distribution in the previous framework. The simplest case corresponds to the previous homogeneous case. We then denote by $\tilde{p}_t = P(\tau_i \leq t|V)$ the unique conditional default probability for time horizon t . According to the homogeneity assumption, the probability of k defaults within the portfolio

($k = 0, 1, \dots, n$) or equivalently the probability that the aggregate loss $L(t)$ equals $\frac{k}{n}$ can be written as $\binom{n}{k} \int \tilde{p}^k (1 - \tilde{p})^{n-k} \nu_t(d\tilde{p})$ where ν_t is the distribution of $\tilde{p}_t$. In other words, the loss distribution is a binomial mixture. Let us denote by φ the density function of a standard Gaussian variable. We can equivalently write $P(L(t) = \frac{k}{n}) = \int_{\mathbb{R}} P(\tau_i \leq t|v)^k (1 - P(\tau_i \leq t|v))^{n-k} \varphi(v) dv$, which can be computed numerically according to a Gaussian quadrature.

An interesting feature of the above approach is the simplicity of distributions for large homogeneous portfolios. According to de Finetti's theorem, the aggregate loss $L(t)$ converges almost surely and in mean to $\tilde{p}_t = \Phi\left(\frac{\Phi^{-1}(F(t) - \rho V)}{\sqrt{1 - \rho^2}}\right)$ as the number of names tends to infinity. In the credit risk context this idea was first put in practice by Vasicek [21]. It is known as the *large portfolio approximation*. Further asymptotic developments such as the saddlepoint expansion techniques have been used, starting from Martin *et al.* [22].

Let us now consider the computation of the aggregate loss distribution for a given time horizon within the Gaussian copula framework without any homogeneity or asymptotic approximation. This is based on the computation of the characteristic function of the aggregate loss. We further denote by $\varphi_{L(t)}(u) = E[\exp(iuL(t))]$. According to the conditional independence upon the factor V , we can write $\varphi_{L(t)}(u) = \int_{\mathbb{R}} \left(\prod_{j=1}^n \left(1 + \Phi\left(\frac{\Phi^{-1}(F_j(t) - \rho_j + nu)}{\sqrt{1 - \rho_j^2}}\right) \left(e^{iu \frac{LGD_j}{n}} - 1 \right) \right) \right) \varphi(v) dv$. The previous integral can be easily computed by using a Gaussian quadrature. Let us also remark that the computation of the characteristic function of the loss can be adapted without extra complication when the losses given default LGD_i are stochastic but (jointly) independent together with the latent variables $V, V_1, \dots, V_n$. The computation of the loss distribution can then be accomplished owing to the inversion formula and some fast Fourier transform algorithm (see Laurent and Gregory [23]). A slightly different approach, based on recursions is discussed in Andersen *et al.* [24]. The previous approach is routinely used for portfolios of approximately 100 names.

Let us remark that since the standard assumption states that the copula of default times is Gaussian, we are able to derive aggregate loss for different time

horizons. This is of great practical importance for the computation of CDO tranche premiums, which actually involves loss distributions over different time horizons.

Conclusion

The computation of the loss distributions is of great importance for credit risk assessment and the pricing of credit risk insurance.

Standard risk measures involved in the credit field, such as the value at risk and the expected shortfall, can be easily derived from the loss distribution. At this stage, let us remark that the risk aggregation of different portfolios is not straightforward when these do not share the same factor. The Basel II framework makes the strong assumption that the same factor applies to all credit portfolios. Moreover, due to some large portfolio approximation, the aggregate losses are comonotonic; they only depend upon the unique factor. In that simplified framework, value at risk and expected shortfall of the wholly aggregate portfolio are obtained by summation owing to the comonotonic additive property of the previous risk measures. This departs from the Solvency II framework in insurance.

As far as the pricing of credit insurance and more precisely of CDO tranches is involved, one needs to compute stop-loss premiums $E[(L(t) - k)^+]$ for different time horizons t and “attachment points” k . According to the semianalytical techniques detailed above, these computations can be carried out very quickly and have now become the standard framework used by market participants.

JEAN-PAUL LAURENT

Credit Scoring *via* Altman Z-Score

Altman Z-Score Model

The recent interest of estimating probability of default for credit products is mainly caused by the Basel II Accord; see Basel Commission on Banking Supervision [1–3]. Such estimation is heavily related to the technique of credit scoring which has a long history in finance. Beaver [5, 6], one of the pioneers in the field, proposes the seminal idea of using the financial ratios for prediction. Beaver is able to discriminate failed firms from non-failed firms 5 years ahead. Altman [7] improves the idea by combining several relevant ratios into a vector of predictors and is the first researcher applying the method of multiple discriminant analysis (MDA). His method becomes the renowned Altman Z-Score, which comprises the main focus in this chapter.

MDA was first introduced by Fisher [8] in statistics to separate multivariate normal populations. Since the separation criterion is a linear function of the multivariate characteristics, MDA is also called the *linear discriminant analysis* (LDA). Applying MDA to predict bankruptcy is equivalent to modeling the joint relationship between the event of bankruptcy of a firm at a specific period and the corresponding firm characteristics (financial ratios) collected immediately before that period.

Specifically, let I be the Bernoulli random variable with parameter π that is the probability of bankruptcy next year. π is called the *prior probability* of bankruptcy because that is simply a rough guess without using any information. Let $X = (X_1, \dots, X_m)$ be the financial characteristic of the firm this year. The model of MDA assumes $(X|I = 1) \sim N(\mu_B, \Sigma)$ and $(X|I = 0) \sim N(\mu_S, \Sigma)$ where Σ is the common variance–covariance matrix, μ_B and μ_S are the mean vectors for bankruptcy and survival, respectively. Such model gives the posterior probability of bankruptcy in the following form:

$$\Pr\{I = 1|X = x\} = \frac{f_B(x)\pi}{(1 - \pi)f_S(x) + \pi f_B(x)} \quad (1)$$

where $f_B(x)$ and $f_S(x)$ are the probability density functions of $N(\mu_B, \Sigma)$ and $N(\mu_S, \Sigma)$. The posterior

probability can be further simplified to

$$\Pr\{I = 1|X\} = g(-[a_1X_1 + \dots + a_mX_m + \gamma]) \quad (2)$$

where

$$g(t) = \frac{1}{1 + \exp\{-t\}} \quad \text{for any real number } t \quad (3)$$

$$(a_1, \dots, a_m) = (\mu_S - \mu_B)^T \Sigma^{-1}$$

and

$$\begin{aligned} \gamma = \log(1 - \pi) - \log(\pi) + \frac{1}{2}\mu_B^T \Sigma^{-1} \mu_B \\ - \frac{1}{2}\mu_S^T \Sigma^{-1} \mu_S \end{aligned} \quad (4)$$

Note that $g(t)$ is increasing in t . Therefore, for fixed, $\Pr\{I = 1|X\}$ is a decreasing function of the linear combination $a_1X_1 + \dots + a_mX_m$. Such linear combination is called the *Z-Score* by Altman [7]. That is, the higher the Z-Score, the less likely the firm will default.

In Altman [7], π is set to be 0.5 because there is no extra prior information of bankruptcy other than X . The other parameters of the model, Σ , μ_B , and μ_S , are estimated by the method of maximum likelihood from a data set, which is a matched sample of bankrupt and nonbankrupt firms. In fact, the bankrupt group was all manufacturers that filed bankruptcy petitions under Chapter 10 from 1946 through 1965. It is clear that a 20-year sample period is not the best choice since the financial ratios X_j do shift over time. A more appropriate sample should consist of the firm characteristics in the same time period t and the bankruptcy/survival indicators in the following period $(t + 1)$. However, such an ideal sample was not available because of data limitations at that time. To remedy the inhomogeneity of the bankrupt group owing to industry and size differences, Altman [7] carefully selects the nonbankrupt control firms such that the firms in the overall data set were stratified by industry and by size, with asset size range from \$1 to \$25 million (see Altman [7, pp. 593–594] for details). Altman [7] begins the MDA with $m = 22$ potential variables and finds that the best bankruptcy prediction is given by the Z-Score from the following five variables:

X_1 : Working capital $\div$ total assets

X_2 : Retained earnings $\div$ total assets

X_3 : Earnings before interest and taxes $\div$ total assets

X_4 : Market value of equity $\div$ book value of total liabilities

X_5 : Sales $\div$ total assets

Here, “total assets” is referred to the sum of all tangible assets (excluding the intangibles) of the firm while the working capital is the difference between current assets and current liabilities. Therefore, X_1 measures the net liquid assets of the firm relative to the total capitalization.

For X_2 , “retained earnings” is the total amount of reinvested earnings and/or losses of a firm over its entire life. It is also known as the *earned surplus*. Note that adjustments should be applied to handle the case of substantial reorganization and/or stock dividend. It is easy to see that X_2 measures the cumulative profitability over the life of the company. Besides, X_2 can also be viewed as a measure of the leverage of a firm. Firms with high X_2 levels financed their assets through retention of profits; they have not utilized much debt. Therefore, X_2 highlights the use of either internally generated funds for growth (low-risk capital) or other people’s money (OPM) – high-risk capital.

X_3 is a measure of the productivity of the firm’s assets, independent of any tax or leverage factors. Since a firm’s ultimate existence is based on the earning power of its assets, this ratio appears to be particularly appropriate for studies dealing with credit risk.

It should be noted that the market value of equity in X_4 is the total market value of all shares of preferred stock and common stock while liabilities include both current and long-term obligations. The measure X_4 shows how much the firm’s assets can decline in value (measured by market value of equity plus debt) before the liabilities exceed the assets and the firm becomes insolvent. Last but not least, X_5 is the capital turnover ratio and it quantifies the sales-generating ability of the firm’s assets.

From the selected data set and the chosen variables, Altman [7] estimates the Z-Score in the form of:

$$Z = 0.012X_1 + 0.014X_2 + 0.033X_3 + 0.006X_4 + 0.999X_5 \quad (5)$$

Although γ in equation (2) could be determined by the method of maximum likelihood and the

corresponding posterior probability could be used to predict bankruptcy, Altman [7] investigates the range of Z and realizes that all firms with $Z < 1.81$ in the study defaulted and all firms with $Z > 2.675$ in the study survived. Two decision rules are derived from such an observation:

1. Predict that the firm is going to bankrupt if $Z < 2.675$. Otherwise, the firm is going to survive.
2. Same as rule (i) but using 1.81 as the cutoff.

Note that although the Z-Score above is computed using Fisher’s approach of LDA and the method of maximum-likelihood estimation, the above decision rules and cutoffs are different from the original Fisher’s proposal that solely depends on the conditional probability $\Pr\{I = 1|X\}$. Moreover, the performance of the above Z-Score is analyzed by Altman and Hotchkiss [4, p. 244] for some data observed after 1968. They examine 86 distressed companies from 1969 to 1975, 110 bankrupts from 1976 to 1995, and 120 bankrupts from 1997 to 1999. Using a cut-off score of 2.675, the successful rates of correct type I bankruptcy prediction (those firms classified as bankrupt will default in the next period of time) are 82, 85, and 94%, respectively. However, the rates of type II error (classifying the firm as distressed when it does not go bankrupt or default on its obligations) could be as large as 25%. Using rule 2 could reduce the rates of type II error although the overall error resulted from rule 1 is smaller.

To reduce both type I and type II errors, Altman and Rijken [9] suggest applying log transformation on the retained earnings/total assets and equity/debt ratios. They argue that the high error rates are caused by the fact that US firms are far more risky today than in the past. This higher risk is manifested in the deterioration of a number of financial indicators in the Z-Score model, particularly the retained earnings/total assets and equity/debt ratios. The log function scaled these two variables to be more comparable to the other variables.

Private Firms and Emergent Markets

For private firms, Altman [10] suggests replacing X_4 by the ratio of book value of equity to the total equity and he obtains the following Z-Score:

$$Z' = 0.00717X_1 + 0.00847X_2 + 0.03107X_3 + 0.0042X_4 + 0.998X_5 \quad (6)$$

with the lower and upper thresholds being 1.23 and 2.90.

Since X_5 (the capital turnover ratio) is more industry sensitive than the others, it may be more appropriate to estimate the Z-Score model without the corresponding term under some situations. For example, Altman *et al.* [11] evaluate the Mexican firms that have issued Eurobonds denominated in US dollars by using such a model. They also set X_4 as the book value of equity in this case. See Altman and Hotchkiss [4, Chapter 12] for more details about the application to the emergent markets.

Concluding Remarks

In summary, while MDA is a model for the joint relationship between I (the indicator of default) and X (the firm characteristic), the key prediction equation (2) is phrased in terms of a conditional distribution, which can be estimated by using the methodology of logistic regression (*see Risk in Credit Granting and Lending Decisions: Credit Scoring; Logistic Regression*). The advantage of applying the technique of logistic regression is that the empirical results are theoretically sound even if X is not jointly normally distributed, given I . Although Efron [12] states that statistically MDA should outperform the logistic regression if the normality of X holds, one can easily check that the explanatory variables in Altman [7] and other Z-Score applications are rarely normal.

The methodology of logistic regression can be phrased in terms of Z-Score in the following form, given $X = (X_1, \dots, X_m)$,

$$Z = \gamma + a_1 X_1 + \dots + a_m X_m + \varepsilon \quad (7)$$

where ε is a random variable whose cumulative distribution function is given by the logistic function g . I is defined as $I\{Z < 0\}$ such that

$$\begin{aligned} \Pr\{I = 1|X\} &= E[I|X] \\ &= \Pr\{\gamma + a_1 X_1 + \dots + a_m X_m + \varepsilon < 0\} \\ &= \Pr\{\varepsilon < -\gamma - a_1 X_1 - \dots - a_m X_m\} \\ &= g(-[\gamma + a_1 X_1 + \dots + a_m X_m]) \quad (8) \end{aligned}$$

The maximum-likelihood estimate of $(\gamma, a_1, \dots, a_m)$ can be efficiently computed via Fisher scoring method. Moreover, the asymptotic inference could be

implemented easily. Similar computations could also be performed for the case of ε being standard normal, which corresponds to probit regression. See McCullagh and Nelder [13] for computational and statistical details of both models. It should be noted that the assumption of probit regression is substantially different from that of MDA even though they both involve normality. The MDA assumes joint normality of the $(X_1, \dots, X_m)$ while the probit regression assumes " $(X_1, \dots, X_m)$ " is conditionally normal. There is no obvious equivalence between these two models.

The logistic regression model has been applied to bankruptcy prediction by Ohlson [14]. Other statistical techniques include quadratic discriminant analysis as in Altman *et al.* [15], recursive partitioning in Frydman *et al.* [16], neural networks in Altman *et al.* [17], and many others in various chapters of Trippi and Turban [18].

In addition to the statistical approach, the Moody's KMV also developed a way of estimating probability of default (PD) known as EDF^{TM} (expected default frequency), which is closely related to the financial option pricing theory. See Altman and Hotchkiss [4, p. 252] for more discussion on EDF.

Credit Value at Risk

Definition and Computation

According to Jorion [1], banks allocate roughly 60% of their regulatory capital to credit risks, 15% to market risks, and 25% to operational risks. Thus, credit value at risk deserves much attention because it determines the adequate protection the banks need to prepare for possible adverse conditions.

Consider a credit portfolio (*see Comonotonicity; Credit Scoring via Altman Z-Score; Statistical Arbitrage*) that consists of default-sensitive instruments such as lines of credit, corporate bonds, and government bonds. The corresponding credit value-at-risk (VaR) (*see Credit Risk Models; Default Risk; Extreme Value Theory in Finance*), is the minimum loss of next year if the worst 0.03% event happens. In another words, 99.97% of the time the loss will not be greater than VaR. Mathematically, if L is the loss of the portfolio caused by default events next year, then

$$\Pr\{L > \text{VaR}\} = 0.03\% \text{ or } \Pr\{L \leq \text{VaR}\} = 99.97\% \quad (1)$$

VaR is equivalent to the 99.97 th percentile of L . Note that the credit VaR is measured at the time span of 1 year and is different from the 10-day convention adopted by the market VaR. Moreover, instead of using the worst 1% event as the benchmark of the market VaR, 0.03% is chosen because it is a rating agency standard of granting an AA credit rating (see Saunders and Allen [2, p. 207]).

Single Instrument

To study the computation of VaR for a credit portfolio, let us start with the case of a single instrument. The loss of a single instrument can be decomposed into three components: the default probability (*see Options and Guarantees in Life Insurance; Risk Measures and Economic Capital for (Re-)insurers; Informational Value of Corporate Issuer Credit Ratings; Copulas and Other Measures of Dependency*) of the obligor, a loss fraction, which is called the *loss given default*, and the exposure at

default (*see Default Risk*), which are denoted by PD, LGD, and EAD, respectively. That is,

$$\begin{aligned} L &= X \times \text{LGD} \times \text{EAD} \text{ and } PD = \Pr\{X = 1\} \\ &= 1 - \Pr\{X = 0\} \end{aligned} \quad (2)$$

where L is the default loss and X is the Bernoulli random variable with $\{X = 1\}$ being the event of default. EAD is nonrandom if the instrument is a bond or a line of credit. In particular, for the latter case, EAD would be the maximum amount that can be drawn because the borrowers are most likely to exhaust all possible resources before default. However, there are exceptions such as the counterparty default risk on credit derivative for which EAD is the replacement value of the derivative at the time of default (Bluhm *et al.* [3, Section 12.4]). For the sake of simplicity, EAD is assumed to be nonrandom in the subsequent discussion.

LGD is the portion of EAD that gives real negative impact in case of default. LGD is usually less than 1 because many default obligors are originally backed up by some mortgages or securities and a proportion of loss could be recovered by selling the guarantees. The recovered portion of default loss is commonly expressed as a percentage of EAD. Such a percentage is called the *recovery rate* and is related to LGD by

$$\text{Recovery rate} = 1 - \text{LGD} \quad (3)$$

The magnitude of the recovery rate is tied to the value of the collateral properties at or after the time of default. Also, the recovery rate depends on the nature of the instrument: only the loss on the principal can be claimed, but not the loss on coupon interest, when the debtor of a corporate coupon bond bankrupts (see Allen [4, p. 329]). Moreover, the seniority of the debt holder in claiming loss significantly affects the recovery rate. In fact, Moody's published figures for 1982–2003 show that senior secured debt holders had an average recovery rate of 51.6% while junior subordinated debt holders had an average recovery rate (*see Compensation for Loss of Life and Limb; Credit Migration Matrices*) of only 24.5% (Hull [5, p. 483]).

An important empirical fact about PD and LGD: they are positively correlated, that is, PD and the recovery rate are negatively correlated. Hamilton *et al.* [6] fit the following regression to the annual

default data from 1982 to 2003 and obtain $R^2 = 0.6$.

$$\begin{aligned} \text{Average recovery rate} &= 50.3\% - 6.3 \\ &\times \text{average default rate (4)} \end{aligned}$$

Since the average recovery rate can be predicted from the PD by using the above regression, the task of evaluating VaR is reduced to the determination of PD, which can be accomplished by the following two approaches:

1. Use Merton's firm-value model (*see Default Correlation*) to back out the risk-neutral PD from the observed equity price. Then, convert the risk-neutral PD to the physical PD by technology similar to the *Expected Default Frequency*TM (or simply EDF) developed by KMV Corporation. See Crosbie [7] or Hull [5, pp. 489–491].
2. Use the credit ratings of external agencies and set the PD for the company of interest to the PD of the corresponding credit class.

Note that although the risk-neutral (*see Equity-Linked Life Insurance; Optimal Risk-Sharing and Deductibles in Insurance; Options and Guarantees in Life Insurance; Mathematical Models of Credit Risk*) PD of a corporate obligor could also be obtained by using the difference between its bond yield and a "risk-free" bond yield (Hull [5, p. 484]), there is no easy way to convert such implied PD into physical PD.

Portfolio

For a credit portfolio of more than one instrument, the default loss is the sum of losses caused by the default events of the various obligors involved. The main issue in computing VaR for a credit portfolio is that the joint default probability for two obligors in general does not follow the law of independence. In fact, companies in the same industry or country tend to default together within a relatively short period of time. This tendency is also known as the *credit concentration, default concentration, or default correlation*.

Moody's KMV and CreditMetrics both try to estimate the joint default probability by using the technology of the copula. To illustrate the idea, let us consider a portfolio of two instruments whose Bernoulli random variables for default are denoted

Table 1 Annual probability transition matrix of credit ratings

Current rating	Next rating		
	A	B	Default
A	0.95	0.025	0.025
B	0.05	0.9	0.05
Default	0	0	1

by X_1 and X_2 . Suppose the first and the second instruments are rated as A and B, respectively, and the corresponding yearly transition matrix in Table 1.

From a recent sample of the equity returns of the corresponding obligors, we compute the means (m_1 and m_2), the standard deviations (s_1 and s_2), and the correlation (ρ). We then simulate $(\tilde{R}_1, \tilde{R}_2)$ from a bivariate normal distribution whose mean vector is (m_1, m_2) , the variances are s_1^2 and s_2^2 , and the covariance is $\rho \times s_1 \times s_2$. $\tilde{X}_1$ is set to be 1 if $\tilde{R}_1 < m_1 - 1.96 \times s_1$. Otherwise, $\tilde{X}_1$ is set to be 0. Note that $N(-1.96) = 0.025$ and is equal to the probability of default of class A to which the first obligor belongs. (N is the standard normal distribution function.) Similarly, since $N(-1.645) = 0.05$ and is equal to the probability of default for class B, $\tilde{X}_2$ is set to be 1 if $\tilde{R}_2 < m_2 - 1.645 \times s_2$. Otherwise, $\tilde{X}_2$ is set to be 0. The simulation is repeated many times and each simulated default loss $\tilde{L} = \tilde{X}_1 \times LGD_1 \times EAD_1 + \tilde{X}_2 \times LGD_2 \times EAD_2$ is stored where LGD_i and EAD_i are the loss given default and exposure at default of the i th instrument. VaR is computed as the 99.97th percentile of $\tilde{L}$.

Simulating $(\tilde{R}_1, \tilde{R}_2)$ is called the *method of Gaussian Copula*. As noted before, this method is adopted by both KMV and CreditMetrics with some variations (Bluhm *et al.* [3, Section 12.3]). Please also see Cherubini *et al.* [8] for other copula approaches.

If the number of instruments in the portfolio is large, the number of correlations that needs to be estimated is huge. For example, if there are 100 instruments involved, we have to estimate 100 means, 100 standard deviations, but $100 \times 99/2 = 4950$ correlations. To keep a small estimation error, an extensive history of equity returns is required. However, it is quite unlikely that the properties of the obligors are invariant over a long time. An effective way to handle such overparametrization issue is to employ a factor model. Suppose $R_1, \dots, R_J$ are the equities return for a credit portfolio of J instruments where J is large. Let $F_1, \dots, F_M$ be the factors where

M is relatively small. The following regression is fitted for each R_j :

$$R_j = a_j + b_{j1}F_1 + \cdots + b_{jM}F_M + e_j \quad (5)$$

e_j is a normal random variable with zero mean and standard deviation σ_j . Also, e_j 's are assumed to be independent of each other. $\{F_i\}_{i=1}^M$ could be the industry factor, country factor, regional factor, and any other relevant exogenous factor. The above formulation reduces the number of parameters to be estimated to $100 \times 5 = 500$ for the case of $J = 100$ and $M = 3$. Therefore, the number of observed equity returns required for good estimation is greatly reduced.

After all parameters are estimated, one can simulate $\{\tilde{R}_j\}_{j=1}^J$ by using the factor model, that is, sampling $\tilde{e}_j$ from independent normal distribution whose mean is 0 and standard deviation is σ_j and computing $\tilde{R}_j$ by

$$\tilde{R}_j = a_j + b_{j1}F_1 + \cdots + b_{jM}F_M + \tilde{e}_j \quad (6)$$

Similar to the previous case, $\tilde{X}_j$ is set to be 0 or 1 by matching the observed transition probability to default. VaR is computed as the corresponding quantile of the simulated portfolio default loss $\tilde{L} = \tilde{X}_1 \times LGD_1 \times EAD_1 + \cdots + \tilde{X}_J \times LGD_J \times EAD_J$.

Stress Testing

Stress testing (*see Operational Risk Modeling; Reliability of Consumer Goods with "Fast Turn Around"*) is the procedure of checking the robustness of VaR under different hypothetical changes to the current situation. Typical examples include perturbation of the model parameters, economic downturn of the country or region, deterioration of the business environment of industry, or the downgrade of specific obligors' credit profiles. One can check the changes in VaR under different scenarios. Another equivalent way is to fix VaR and observe how the tail area of L is affected. A systematic account can be found in the Bank of International Settlement document of "Stress testing at major financial institutions: survey results and practice", which was prepared by their Committee on the Global Financial System in 2005.

Allen [4, p. 350] highlights the country risk factor and suggests this factor has to be treated with special care. Such risks can manifest in many forms: they

can range from war and revolution to imposing defensive exchange controls by the government. They cause all firms, individuals, and government bodies in that country to be rated as poor in credit or even as defaulters. Scenario analysis of VaR can be performed by subjective assessment and using data from similar past political disruption in other countries. See Calverley [9] for details.

Implementation Details

The above presentation is very brief because we only want to show the basic idea of VaR without going into the details. In this last section, we aim at providing a hint of complexity in the reality:

- Many commercial banks are holding credit portfolios that consist of illiquid traditional loans. Estimation of the marginal PDs and the default correlations rely on internal rating systems that are very different from the approach we presented above. See Allen *et al.* [10, Chapter 4].
- Although many banks have a strong desire to apply credit VaR to both trading and loan books in an integrated manner, some of the cumbersome barriers are the differences in accounting treatment, variation of technology platforms, and the illiquid factor noted above. The banks may involve fundamental changes in organizational structure in order to implement consistent integrated risk-management systems.
- The factor model in the section titled "Portfolio" assumes that all equity returns and factors can be collected and organized in nice rectangular forms that are ready for regression routines. However, in reality, there are values missing everywhere. One of the reasons is that the sampling frequencies of the factors and those of equity returns are in general different. Another issue is that some of the companies involved in the portfolio could have become public very recently and the equity return may not be available before initial public offering (IPO). Statistical techniques, such as EM algorithm of Dempster *et al.* [11] and data augmentation algorithm of Tanner and Wong [12], can be employed to impute the missing values and estimate the model parameters.
- Similar to market VaR, backtesting is one of the goals to be achieved in addition to stress testing. However, the time span of credit VaR is typically

1 year and it is hopeless to collect enough historic credit loss data for validation purpose. Lopez and Saidenberg [13] suggest backtesting by cross-sectional simulation, which is essentially a variation of bootstrap, i.e., evaluation based upon resampled data. See Efron and Tibshirani [14].

Cross-Species Extrapolation

Overview and Conceptualization

Extrapolation may be thought of as an inferential process by which unknown information is estimated from known data. Originally, mathematical usage involved any method of finding values outside the range of known terms or series by calculation [1–3] and was extended to a nonmathematical sense [4]. Earlier the usage of the term had a negative connotation, implying unwarranted speculation, but the term came to be used widely in scientific reasoning [5].

Cross-species extrapolation (CSE) has a rich history in biology and its validity underlies the majority of current research in human health in which nonhumans or cell systems are used to model disease or injury. In toxicology, CSE is used in the effort to estimate the effects of toxicants in one species (the target species), usually human, from knowledge of the effects of the toxicant in another species (the source species) (*see Cancer Risk Evaluation from Animal Studies*).

CSE may be conceptualized as three components: (a) *dose estimation*: given exposure to a toxicant, estimate the magnitude of the internal dose in the target species from the source species by comparative pharmacokinetics; (b) *effects prediction*: given internal dose in the target species, estimate the magnitude of effect from the source species by comparative biology; and (c) *quantification*: make the estimates numerically, bounded by confidence limits.

Dose Estimation

Principles

With few exceptions, effects of a toxicant are produced by some function of the dose of the toxicant and/or one or more of its metabolites at the organ being impacted [6, 7]. This “internal dose” is the result of the absorption, distribution, biotransformation, and elimination of the dose applied to the subject. These are determined by physical processes and described by pharmacokinetic equations. These processes can be described by a physiologically based pharmacokinetic (PBPK) model with

appropriate parameters and used to estimate the amounts of toxicants delivered to tissues, their biotransformation, and elimination [8].

Given the knowledge of applied and internal dose for some toxicant in the source species, the goal of PBPK modeling is to estimate internal dose in the target species where it may not be measured. Once a PBPK model is developed and evaluated against data in the source species, then it is presumed, in the simplest case, to be a matter of rescaling the parameters of the model to appropriate values for the target species. It is frequently assumed that the best estimate of parameters is directly proportional to body surface area [9]. Surface area may be approximated by taking body weight to the 0.75 power [10]. Such “allometric scaling” methods have been generalized for many physiological parameters [10, 11].

If the physiology or biotransformation processes differ in principle between the two species, however, then the structure of the PBPK model must be altered in the target species instead of simply rescaling. Assuming that PBPK models of appropriate form with accurate parameters are available, it is possible to estimate internal doses for various organs in the target species, ideally with the help of data from the source species. By this means, one can determine whether a particular effect in the two species from some fixed applied dose differs in magnitude because the internal doses differ or because the affected organs in the two species differ in sensitivity.

Practice

Remarkable accuracy of internal dose estimation can be achieved by PBPK models if applications are restricted to simple cases. One common restriction in practice is to parameterize the model for a static baseline case, i.e., where the organism is in some unchanging physiological state. Parameters, however, vary across individuals and thus it may be desirable to measure important parameters on individual subjects to evaluate and utilize a model (e.g., Benignus *et al.* [12] for carboxyhemoglobin or Pierce *et al.* [13] for toluene). Temporal variation of parameters as the organism changes its activity, enters new environments, ages, etc., can also be described to increase precision of estimation [14, 15] in such cases.

The correctness of the model form depends on knowledge of the relevant physiology and its completeness depends on knowledge and upon choice of detail. See Clark *et al.* [16] for evaluation criteria. Even if the form is correct and detailed enough for the purpose at hand, it must be recognized that parameter values are typically means of observations, which vary over individual subjects, time, and measurement error. Thus it is not usually sufficient to predict only the mean internal dose. The confidence limits in the predicted internal dose must be given.

One of the proposed methods of estimating variance and hence confidence limits is to determine, either analytically [17] or iteratively (by Monte Carlo simulation) [18] the variation in predicted internal dose by combining the known variance/covariances of all of the model parameters. The variances of parameters are sometimes known from experiments, but covariances are usually not known. Assuming zero covariances results in overestimation of the variance in the estimated internal dose. A Bayesian approach (see **Bayesian Statistics in Quantitative Risk Assessment**) to simulation is sometimes taken in which variances and covariances are given *a priori* values by expert consensus and then reestimated from data, presumably improving the final estimate [13].

A difficulty, both conceptual and practical, in estimating variance in the predicted mean internal dose is the complexity of a PBPK model, which, in turn, leads to large, complex simulations or analyses. This difficulty can be mitigated by first performing sensitivity analyses on the PBPK model to determine the most sensitive parameters [19]. Only the most influential parameters and those that influence them then need be included in the Monte Carlo simulation. This procedure does involve arbitrary judgment as to what magnitude of influence is important enough to be included.

Even when the above assessments of a PBPK model's correctness are satisfied, the ultimate criterion of quality is a demonstration that the model predicts correctly in a known case. Criteria for the "correctness" of a model's estimation are frequently implicit, but it is sometimes inferred that the model is verified if estimates from the model fall within the confidence limits of the measured internal dose. It is rare that model predictions are compared to empirical data by appropriate repeated-measures, mixed-model statistics [15].

Predicting Effects of the Internal Dose

Principles

Effect of toxicants has been studied at the whole organism level, at the organ level, or at many reductionistic levels, including cellular, molecular, and genetic. Studies at whole organism and organ levels tend to be the most useful for regulatory purposes such as identifying health effects, determining dose–effect relationships, and conducting benefit–cost analyses. Reductionistic data tend to be useful for constructing theory and explaining effects. They can be used to defend interpolation between observations or predict other effects not previously suspected from more macroscopic approaches.

Mathematical models have been constructed to describe the normal physiology of the body. Such models may be fragmentary, to describe the function of various organs or systems of cells [20], or they may be more complete, approaching models of the entire body physiology, e.g., The Modeling Workshop (<http://physiology.umc.edu/themodelingworkshop/>). More ambitious work is in progress to include reductionistic work from the genome to whole body function [21].

When dose–effect models are constructed from experiments with a source species, then presumably it becomes possible to model observed effects in mechanistic terms. If sufficient physiological information exists about the same organ systems in the target species, then the model may be scaled and appropriately changed in form to predict the effect of the toxicant on target organs. Such rescaling frequently involves estimation of relevant organ volumes and process rates (see discussion, above, of rescaling in PBPK models). Mechanistic approaches to effect estimation have been called *biologically based dose–response (BBDR) models* [22]. This approach would be the usual practice of comparative physiology, but mathematically expressed to give numerical predictions.

Practice

The process of constructing a BBDR model is similar to constructing a PBPK model, but usually more complex. Not only must the normal functioning of a physiological subsystem be known in sufficient detail to quantitatively model it, but the mechanism

by which toxic effects are produced must also be known. It is also necessary to apply the same criteria of quality to the modeling process [19]. For well-studied systems, e.g., certain kinds of cancer, both the physiology and cellular process are comparatively well known [23]. For example, cellular processes have been combined with general physiological and dosimetric information to construct a model for estimating the dose–effect curve of nasal cancer induced by formaldehyde exposure [24, 25]. In addition to good prediction of observed data, the model provided defensible interpolations between baseline (no effects) and the lowest-exposure empirical data and thus refined the probable form of the dose–effect relationship.

Other cases of useful BBDR models might be cited, usually in cancer effects, but there are few such cases. On a less microscopic level, physiological models have been constructed for estimating effects of simultaneous exposure to multiple toxic gases [14, 26] and simultaneous variation in environmental conditions, e.g., temperature, altitude, and physiological gases (<http://physiology.umc.edu/themodelingworkshop/>). The lack of more such models can be attributed in part to insufficient information about (a) normal physiological functioning in many organ systems, e.g., the central nervous system and (b) mechanisms of the toxic effects for many substances.

Quantitative Extrapolation

Mechanistic Approach

In a systematic sense, PBPK and BBDR models are used to adjust the magnitude and form of data from the source species so that they may be directly applied to the target species. These steps assume that physiological knowledge is adequate to make such adjustments. Unfortunately, such knowledge is not available for some organs, e.g., the central nervous system. Even if such limits of knowledge did not exist, the numerical CSE process remains an inferential leap across species that cannot be verified in cases where such an estimate would be most useful, i.e., the case where toxicant effects in humans cannot be measured. Next in importance to the numerical inferences are the confidence limits about the inferences. From the above discussions, it is evident that confidence limits based on the physiological models are

often difficult to estimate. It seems, because of these limitations, that for many physiological systems and for many important toxicants, the PBPK and BBDR approaches to CSE will not prove to be an immediately adequate approach. Therefore, an alternative practice empirically based on CSE, may be useful.

Empirical Approaches

Traditional. The traditional empirical approach can be characterized as (a) experimentally finding an effect of some suspected toxicant in a source species, (b) assuming that the same effect would occur in the target species, and (c) estimating the magnitude of the effect or the probability of its occurrence in the target species. Experiments to assess effects of a toxicant in the source species may range from binary decisions of hazard to full empirical dose–effect studies. The kind of data available from the source species affect the extrapolation strategy.

Decisions about regulation of a toxicant are frequently made from some scalar measurement of effect that is intended to characterize the highest permissible exposure or the lowest exposure to produce detectable effects. Among these, the benchmark dose [27] (*see Benchmark Dose Estimation*) is the more statistically informed. Making the inferential leap to the target species is usually accompanied by assignment of so-called between species “uncertainty factors” [28] that are intended to adjust the magnitude of effect observed in the source species to protect the target species. Uncertainty factors can take on various magnitudes, often depending upon expert opinion that yield estimates that are unsatisfyingly uncertain.

Formalization of Inference. The inferential leap to the target species can, however, be performed with more quantitative methods if appropriate data are available. Here, a more general approach to CSE will be followed. The method [29] involves extrapolating dose–effect curves with confidence limits from source to target species and requires the availability of dose–effect data in both species for some toxicants of a particular class. The phrase “class of toxicant” can be given logical *a priori* qualitative meaning, e.g., toxicants that have highly similar modes of action or chemical structure, etc.

The steps for empirical CSE for all members of a class of toxicants for which adequate data exist in both species are as follows. First, for a

given effect, construct the dose–effect function in the source and target species along with the empirical confidence limits. Then, using the two dose–effect equations and their confidence limits, compute a dose-equivalence equation (DEE), which gives a dose in the target species that is known to produce an effect of equal magnitude as any given dose in the source species. The confidence limits around the DEE can be computed [29]. Thirdly, given that the DEEs are available for several members of a toxicant class, the parameters of the DEEs can be used to form a (possibly multivariate) distribution. A final, inferential step may now be made for some member of the toxicant class for which data in the target species are absent.

The inferential leap in empirical CSE depends upon the plausibility of the hypothesis that DEEs are numerically the same for all members of a toxicant class, regardless of the relative potency of each of the members. By this hypothesis, even if the potency varies across the toxicants of a class, the relative potency across species is invariant. If this hypothesis is plausible, then the dose–effect curve in the source species can be used to give the most informed estimate of the dose–effect curve in the target species for any toxicant of the class, by application of a DEE constructed from the mean parameter values of the previously defined distribution. The confidence limits about such an extrapolation may also be computed.

The utility of this method for empirically based CSE depends (a) upon the existence of sufficient data to form a distribution of DEE parameters for a particular toxicant class and (b) the plausibility of the construct of “class of toxicants”. A first-step definition of a class of toxicants can be constructed from whatever *a priori* information is available. After obtaining the distribution of the DEE parameters, the plausibility of the class definition can be evaluated by demonstrating that the DEE parameters do not statistically differ among members of the class. The mean parameters of the DEE from the chemical class can then be assumed to represent all members of that class, including those that have not been tested. In this manner, experimental data, gathered from the source species, on an unknown chemical of that class can be used to predict effects in the target species. It is possible to consider a number of variants on this procedure. If, e.g., sufficient dose–effect data did not exist for construction of DEEs, the process could be

reduced to include whatever data were available, e.g., benchmark doses.

Advantages of the Empirical Approach. In addition to the possibility that sufficient knowledge exists for some empirical CSE, some of the problems that are inherent in PBPK and BBDR modeling are not as intractable, e.g., it may be argued that empirical confidence limits for dose–effect curves are the end result of all of the sources of variation that enter into the PBPK and BBDR models. Thus, if the confidence limits are estimated empirically, the need to know extensive model parametric data and variance/covariances are greatly reduced. On the other hand, the possible biases (systematic errors) in estimates of internal dose or effects cannot be ignored in empirical CSE. The effect of biases may be studied *via* a comprehensive sensitivity analysis [30].

Similar to mechanistic approaches, in empirical approaches too adequate knowledge is scarce. Data for particular toxicants in both species typically exist (if at all) as individual publications and can sometimes be combined *via* meta-analyses (*see Meta-Analysis in Nonclinical Risk Assessment*). Only one example of empirical DEE [31] has been published and there is no case of dose–effect CSE in literature. Perhaps, knowledge gaps in mechanistic methods can be solved by empirical methods and *vice versa* because of a complementary state of knowledge. Clearly, however, both methods suffer the same kinds of limitations.

Evaluation and Recommendation

From the above discussion, it is apparent that the area of quantitative CSE holds much promise but, compared to the promise, has managed to deliver little. The reasons for this are not simple to categorize, but can be broadly stated as “lack of sufficient knowledge”. Fortunately, one of the most important functions of explicating the goals and methods of CSE is didactic. Constructing appropriate methods quickly leads to the discovery of specific, well-defined needs.

Mechanistic Approaches

The outstanding need with regard to dosimetry is for PBPK models, which will be usable in applied cases, e.g., (a) simultaneous exposure to multiple

toxicants; (b) environments in which multiple important parameters vary as a function of time; (c) applications in which gender, age, health, species, etc., would affect the parameters; and (d) more comprehensive representation of the metabolic processes for many toxicants.

BBDR models fare less well in successful implementation and utility. It is tempting to claim that such modeling is newer, but in a general physiological overview, this is not the case. It is their application to quantitative description of toxicant effects that is more recent. Some impediments to the development of BBDR models have been ameliorated lately, e.g., larger, faster computers and measurement devices permitting the quantification of more detailed and multivariate measurements in physiological systems. A major problem in construction of BBDR models is, however, the consequence of including such increasingly detailed information. In order to synthesize all of the new knowledge into a whole system, theorists who are also well versed in mathematics and computation are required, in addition to rigorous experimentalists.

In all cases where BBDR models have been successful in toxicological CSE, the models have been specific to a particular toxicant and a particular organ. If the information about health effects of toxicants is to be useful in evaluating the overall consequences of various exposures, such parochialism will not suffice. Toxicants have multiple effects, all of them contributing to the evaluation of the cost of health effects. To evaluate the impact of toxicants on public health, BBDR models for CSE must eventually approach whole body models with sufficient detail to simulate multiple toxicants, each with multiple effects. Of course, such grandiose modeling schemes are far in the future, but it is the philosophy of the approach that is important to guide progress.

Empirical Methods

Systematic empirical methods for CSE can be considered as stopgaps for CSE until mechanistic modeling becomes available, but it is important to note that until it becomes possible to estimate confidence limits around the means of health effects estimated by mechanistic means, empirical CSE methods will be essential. Of the approaches to quantitative CSE, empirical methods that employ dose–effect information have been least employed. This is, in

part, due to a reliance in the regulatory community on point estimation of lowest safe exposures to toxicants. These methods were developed to use currently available information and technology.

Sufficient data exist in the literature to construct DEEs for some members of limited classes of toxicants. No formal effort has been made to do so. The empirical data for a broad range of toxicants is lacking. Certainly, if multiple toxicant exposure is considered, the data base is inadequate.

Conclusions

1. Approaches to CSE are needed to adjust data from the source species by dosimetric and mechanistic methods so as to translate the data into the domain of the target species.
2. Methods exist for estimating the internal dose of a target species on the basis of data from a source species (PBPK models).
3. Methods for estimating the target species effects and confidence limits have been proposed. They can be broadly categorized into mechanistic from physiological theory and empirical/statistical from existing dose–effect data.
4. For the most part, the data for numerical extrapolation do not exist, either in theoretical models or in empirical methods.
5. The methods and schemes proposed for formal extrapolation form a framework to guide the development of new methods and new research to solve the problems.

AND PHILIP J. BUSHNELL

Cumulative Risk Assessment for Environmental Hazards

As part of their existence, people and ecosystems are commonly exposed to a diverse and dynamic mixture of environmental agents, including biological (e.g., *Mycobacterium tuberculosis*), chemical (e.g., organochlorine pesticides), physical (e.g., UV radiation), and psychosocial (e.g., overcrowding) stressors. *Cumulative risk* refers to the combined probability of harm from exposure to all of these different kinds of stressors across all relevant exposure pathways and routes. In the case of humans, there is solid scientific evidence, for example, documenting increased cancer risks from concurrent exposure to tobacco smoke (see **Environmental Tobacco Smoke**) and asbestos (see **Asbestos**), to tobacco smoke and radon (see **Radon**), and to aflatoxin and hepatitis B infection. While researchers and risk assessors have known for decades about the possibility of enhanced cumulative risk from exposure to multiple environmental stressors, progress in understanding responsible biological mechanisms and developing suitable quantitative methods for risk assessment have been slow because of insufficient regulatory attention, technological limitations, and scarce funding. Consequently, realistic assessment of cumulative risks from exposure to real-world mixtures of environmental stressors is limited in most cases by a paucity of relevant data and a lack of scientific understanding [1, 2].

Cumulative risk assessment involves the analysis, characterization, and possible quantification of the combined risks to human health [3, 4] or environmental systems [5] from exposure to multiple environmental stressors (see **Environmental Health Risk; Environmental Hazard**). It is a tool for organizing and evaluating risk-related information so that risk assessors and risk managers can make realistic determinations of the scope and magnitude of amalgamated adverse effects from environmental mixtures [1, 2]. Compared to traditional human risk assessment, cumulative risk assessment is different in four ways: it may be qualitative (rather than quantitative) depending on the circumstances; the combined effects of more than one agent are evaluated; the emphasis is on actual (real) at-risk populations

rather than hypothetical individuals or scenarios; and assessments can involve more than just chemicals.

The framework for assessment of cumulative risks, as shown in Figure 1, encompasses three interrelated and generally sequential phases: (a) planning, scoping, and problem formulation; (b) data analysis; and (c) interpretation and risk characterization [1, 2]. A team of researchers, risk assessors, and stakeholders work together in the first phase to determine the goals, breadth, depth, and focus of the assessment. Outcomes of this step include a conceptual model that identifies the stressors to be evaluated, the adverse endpoints to be assessed, and the nature of relationships among exposures and effects, as well as an analysis plan that specifies the data needed, the approach to be taken, and the types of results expected in subsequent phases. In the second phase, exposure profiles are developed, risks are estimated, and variability and uncertainty are discussed. During this step it is imperative to describe the interactions among stressors and their effects on mixture toxicity, and identify potentially vulnerable populations. The products of the analysis phase are either a quantitative or qualitative estimate of cumulative risk along with a description and estimation of related uncertainty and variability. In the final phase, the risk estimates are explained, overall confidence in the estimates is defined, effects of key assumptions on results are described, and a determination is made as to whether the assessment met the goals and objectives set forth in phase one. Although cumulative risk assessment is still in its infancy, the literature contains numerous examples of diverse methods used to evaluate combined effects on human health [6–10] and ecological systems [11–14] (see **Ecological Risk Assessment**).

There are several different theoretical approaches for estimating risk from exposure to multiple stressors [1, 2]. For example, by assuming toxicologic independence or similarity it is possible to approximate the joint exposure–response relationship for a mixture of environmental stressors using only information on individual stressors. Assuming toxicologic independence means that toxicity modes of action are biologically independent and there are no pretoxicity interactions (e.g., metabolic inhibition). By assuming toxicologic similarity, stressors can be grouped according to a common mode of action and “dose addition” (e.g., relative potency factors, toxic equivalency factors) used to estimate cumulative risk [1, 2].

Figure 1 The three interrelated and generally sequential phases of cumulative risk assessment. (a) Planning, scoping, and problem formulation phase; (b) analysis phase; and (c) interpretation and risk characterization phase [Reproduced from [2]. National Institute of Environmental Health Sciences, 2007.]

“Response addition”, like dose addition, assumes there are no interactions among mixture constituents because they either act independently or have different target organs so that the presence of one stressor does not affect the toxicity of another. The response addition method has historically been used primarily for chemical carcinogens [1, 2].

Dose–response evaluation (*see* **Dose–Response Analysis**) can occur separately from the exposure assessment step if certain simplifying assumptions are made, such as all exposures occur continuously, exposure sequence is unimportant, and mixture composition is constant. It is then possible to set health-protective action levels using estimates of upper bounds on toxic potency caused by exposure, and lower bounds on the acceptable (safe) exposure level [1, 2].

In cases where there are divergent data from different sources on exposure (e.g., time-weighted *versus* continuous) and toxicity (e.g., quantitative *versus* qualitative), indices can be used to convert dissimilar multivariate data into a single number. The hazard index (HI) for noncarcinogens (systemic toxicants) is the most common example of this approach for cumulative risk assessment. Each HI is calculated for a specific target organ (e.g., respiratory, neurological, and cardiopulmonary) by summing the hazard quotients of each stressor (i.e., the exposure concentration divided by the relevant reference dose or concentration) in the environmental mixture of interest. A mixture $HI \leq 1$ is generally interpreted to mean that the mixture is unlikely to be harmful, while a $HI > 1$ indicates the need for further evaluation [1, 2].

Selecting an approach for conducting a cumulative risk assessment depends on a variety of factors, including whether there are interactions among mixture components; the types of interactions (e.g., toxicokinetic and toxicodynamic) that occur; the quality and quantity of available data; and the objectives of the analysis. Application of more than one method may be justified, depending on the circumstances. Moreover, a simple, less data-intensive method may be appropriate for initial screening, while a more intricate and data-intensive method may be appropriate for follow-up analysis [1, 2]. In conclusion, risk assessment in regulatory agencies, particularly the US Environmental Protection Agency (EPA), is currently undergoing a transition. Risk assessors and risk managers are beginning to move beyond their historical focus on command-and-

control strategies, end-of-pipe controls, narrow media-based enforcement, one-size-fits-all regulations, rigid and prescriptive rules, and process-based technology standards. The challenges of the twenty-first century are pushing them to focus more on cooperative and voluntary control strategies, pollution prevention, holistic multimedia approaches, place-based environmental decisions, flexible, easy-to-adjust rules, and outcome-based standards. These changes in regulatory philosophy require complementary changes in risk assessment, and emphasis is shifting away from a narrow focus on single stressors, endpoints, sources, pathways, and environmental media to a more inclusive approach that comprises multiple stressors, endpoints, sources, pathways, and environmental media [1, 2].

Cumulative risk assessment is an essential and inevitable element in this ongoing transition. As more data and better scientific understanding become available about exposures to environmental mixtures, interactions among mixture constituents, and combined effects on human populations and environmental resources, cumulative risk assessment will emerge as a critical tool for risk-based decision making.

Cyber Risk Management

The cyber security landscape is made up of the asset owners, their critical missions, their supporting information systems, and process control systems (collectively called the *user model*), the set of adversaries, their skills, motivations, and resources (collectively called the *adversary model*), the space of all cyber-related attacks (see **Digital Governance, Hotspot Detection, and Homeland Security**), and the space of all cyber attack countermeasures. These different models and spaces are interrelated. The asset owners use information computer networks, information and process control systems to more efficiently achieve their operational missions. The adversaries have motivation, cyber attack skills, and resources to attack the asset owner's critical information and process control systems by exploiting vulnerabilities in the computer technology or operational procedures. Finally, the asset owners can choose to deploy security countermeasures to protect against the cyber attacks; however, each security countermeasure comes at a cost in terms of money, functionality, interoperability, ease of use, etc. So, the asset owner must deploy security countermeasures only when needed. A structured cyber risk-management process helps the asset owner analyze each model and space to determine the appropriate set of cyber security countermeasures. The cyber risk-management process will assess the vulnerabilities to the asset owner's systems, determine the impact to the mission if these vulnerabilities were to be exploited, assess the asset owner's adversaries and their motivation, skills, and resources to mount the cyber attacks that exploit the system vulnerabilities, and estimate the probabilities and expected loss of cyber attacks. Finally, the cyber risk-management process will compare the costs and benefits of adding, deleting, or modifying the cyber security countermeasures.

Definitions

Risk management is the process of measuring or assessing risk, and then determining the appropriate strategy to deal with the risk. Risk is a commodity and can be bought and sold and moved from one location to another. Possible risk-management strategies include combinations of transferring the

risk to another party (e.g., an insurer), decreasing the risk, accepting the risk, or increasing the risk.

Risk assessment is the critical step in risk management of measuring the risk to an organization. Risk assessment typically includes two metrics, the probability of a harmful event, P_e , and the consequences of a harmful event, C_e . Thus, the risk of a particular event is the product of these two components:

$$R_e = P_e \times C_e \quad (1)$$

Cyber risk assessment is the process of measuring the asset owner's risk introduced by the use of computer networks, information systems, and process control systems for mission-critical functions.

Cyber risk is the risk to an asset owner's critical missions introduced by the reliance on computer networks. Cyber risk has two components; nonmalicious events caused by human error, pranksters, or failures in the computer systems, and malicious attacks intentionally caused by intelligent adversaries.

Cyber attacks are a series of intentional, malicious activities executed by an intelligent adversary that exploit vulnerabilities in an asset owner's computer systems with the intent to degrade their critical missions. Cyber attacks typically target either the availability, integrity, or confidentiality of mission-critical information.

Active versus passive: An "active attack" attempts to alter the computer system resources or affect their operation. A "passive attack" attempts to learn or make use of information from the computer system but does not affect system resources (e.g., wiretapping).

Insider versus outsider: An "inside attack" is an attack initiated by an entity inside the security perimeter (an "insider"), i.e., an entity that is authorized to access the computer system resources but uses them in a way not approved by those who granted the authorization. An "outside attack" is initiated from outside the perimeter, by an unauthorized or illegitimate user of the system (an "outsider"). In the Internet, potential outside attackers range from amateur pranksters to organized criminals, international terrorists, and hostile governments.

Attack characteristics are those aspects of an attack against a computer system that determine the level of risk introduced by that attack. The attack

characteristics include the attack objective (the attack usually targets a mission-critical function), the cost to the adversary of attempting the attack, the level of difficulty of the attack, and the level of detection of the attack.

Costing attacks is the risk assessment phase of assigning quantitative values to the attack characteristics.

Threat is the combination of an adversary with an intention to cause harm or damage, the corresponding attack objective, attack techniques, and mission impact.

Cyber adversaries are those groups or individuals that have the motivation and ability to conduct cyber attacks against the asset owner's mission-critical computer systems.

Cyber vulnerability is a flaw or weakness in a computer system's design, implementation, or operation and management that could be exploited to violate the computer system's security policy. Most computer systems have vulnerabilities of some sort, but this does not mean that all the computer systems are too flawed to use. Not every threat results in an attack, and not every attack succeeds. Success depends on the susceptibility of the computer system, the degree of difficulty of exploiting the vulnerability, the skill level of the attacker, and the effectiveness of any countermeasures that may mitigate the vulnerability. If the attacks needed to exploit vulnerability are very difficult to carry out, then the vulnerability may be tolerable. If the perceived benefit to an attacker or impact to the defender is small, then even an easily exploited vulnerability may be tolerable. However, if the attacks are well understood and easily made, and if the vulnerable system is used by a wide range of users, then it is likely that there will be enough benefit for someone to make an attack.

Cyber Risk-Management Workflow

The following list describes a work flow for a generic cyber risk-management process [1]:

1. Characterize mission-critical functions and assets

Identify and quantify the mission criticality of each cyber function and asset. The value of cyber assets to the asset owner far exceeds the replacement cost of the hardware and software. Oftentimes, the true value of cyber assets and functions are best

measured in terms of impact to business continuity. For example, the availability and integrity of a company's accounting software is more valuable to the company than the purchase price of the software package. For each critical cyber asset and function, estimate the loss to the organization if the availability, integrity, or confidentiality of that cyber asset or function is lost.

2. Identify adversaries

Today's critical computer systems must operate in a hostile environment, protecting themselves against a variety of threats. We define *threat* as the combination of an adversary, attack objective, attack technique, and mission impact. *Adversaries* are those groups or individuals that have the motivation and ability to conduct cyber attacks against the asset owner's mission-critical computer systems. Adversaries include hostile insiders or outsiders. The insider may be co-opted by another adversary or be working on his own behalf. Some examples of hostile outsiders include foreign nation states, terrorist organizations, organized crime, hackers, and economic competitors. Modeling the adversary by characterizing the adversary's desire and ability to conduct attacks helps predict adversary behavior. The adversary characteristics include the following:

- (a) Attack objectives – ways of degrading the customer's critical missions.
- (b) Available resources – money, manpower, and time.
- (c) Sophistication – technology and capabilities for conducting difficult cyber attacks.
- (d) Risk tolerance – willingness to take chances and risk failure and detection.

3. Characterize computer system

Defining the system to be analyzed is a crucial step in the cyber risk assessment process. Having a detailed, well-defined system description helps scope the analysis. The system description starts with a mission statement, a concept of operations, and a high-level functional description of the system. More details will be needed for security-critical components and functions. Finally, information flow diagrams and use cases map the system description to the critical missions and help with the risk assessment.

4. Identify attack objectives

Combine the adversary's high-level attack objectives with the system description to derive system-specific

attack objectives (*see Use of Decision Support Techniques for Information System Risk Management*). Because the computer system provides mission-critical functionality to the asset owner, the cyber adversary will harm the organization by attacking the computer system. Example attack objectives include “steal the organization’s proprietary product designs” or “destroy the organization’s engineering database”.

5. Generate attack list

The objective of identifying attacks is not to simply identify some vulnerabilities, but to discover all the effective ways of defeating the security of the computer system. Doing so will identify the true weak points of the computer system. To help identify a comprehensive list of system attacks, the cyber risk analyst should consider the following:

- (a) Start by identifying all the critical missions and corresponding high-level attack objectives, and keep these in mind during the entire process.
- (b) Think about all the ways the adversary could accomplish the attack objective. Think broadly at first, and then fill in the details later.
- (c) Consider using attack trees to structure the thinking [2–5].
- (d) Use comprehensive attack taxonomies that include all of the adversary’s attack capabilities. A good attack taxonomy will include attack capabilities against which the computer system may not have a proper defense. For example, the adversary may introduce an unknown vulnerability into the design of a commercial component using a life-cycle attack [6].
- (e) Combine attack steps from different attack disciplines. For example, the adversary could co-opt an insider, and then use the insider access to launch sophisticated computer network attacks (CNAs).
- (f) Consider the adversary’s attack strategy over time. The adversary may gain access to the system earlier in the life cycle, but may not pull the trigger on the final attack step until much later when the impact will be most devastating to the customer’s mission.

Thinking about all the ways the adversary could break the rules will help the defender identify all

the most serious attack scenarios (*see Multistate Systems*).

6. Quantify risk of each attack

The next step in the cyber risk assessment process is to quantify the risks by scoring the attack steps according to factors that influence the adversary’s attack strategy: attack cost and difficulty, risk of detection, consequences of detection, and the impact of a successful attack. For each identified attack, the cyber risk analyst scores the attack by estimating the resources required to carry out the attack, the capabilities needed to succeed, the degree of difficulty of the attack, and the probability that the attack will be detected.

7. Manage the risk

The final step in the risk-management process (*see History and Examples of Environmental Justice; Syndromic Surveillance*) is to compare alternatives and perform cost/benefit analysis to make trade-offs between adding, modifying, or deleting security countermeasures to most effectively provide security, functionality, and usability within the cost and time constraints of the asset owner. Because of the various costs incurred, cyber security countermeasures should be applied to directly prevent, detect, or recover from the most serious cyber attacks identified during the structured cyber risk assessment. The overall goal is to provide the right balance of cyber security to optimize mission effectiveness for the asset owner.

Cyber Adversary Space

The cyber adversary space includes different classes of adversaries that use a combination of cyber attack techniques to cause harm and inflict damage on the defender’s mission or assets. The following sections describe the cyber adversaries in terms of their observed behavior, their motivations to conduct cyber attacks, their resources available to conduct cyber attacks, their cyber attack skills, and their tolerance for being detected.

Nation States

This class of adversary is a conglomerate of all state-sponsored foreign intelligence services (FISs) and special military units (e.g., an Information Warfare division) that have a potential to attack critical communications and computer systems. Foreign

nation states, whether they be enemy or ally, continuously conduct intelligence operations to defeat the confidentiality of sensitive information. In a crisis or war scenario, the foreign nation state may also conduct special information operations to attack the confidentiality, integrity, and especially the availability of mission-critical infrastructure systems.

Note that it is impossible to characterize the entire spectrum of foreign nation states with a single adversary model. Different nations have vastly different characteristics. For example, some nations are quite belligerent, but do not have sophisticated information warfare capabilities. Other nations might be technically sophisticated, but may be very peaceful. This adversary model attempts to characterize the most significant foreign threats from modern nations, realizing that not all nation states fall into this characterization.

Because nation states behave so differently in times of peace, crisis, and war, this adversary model separates this class of adversary into two subclasses; the peacetime adversary is described by the FIS, and the wartime adversary is described as the Info Warrior.

Foreign Intelligence Service (FIS)

The FIS represents those nations that conduct active espionage against other nations.

- *FIS motivation* – The primary attack objective of the FIS is intelligence gathering. The FIS will target computer systems that store or process information with high intelligence value.
- *FIS resources* – The FIS adversary has an extremely high level of resources available for cyber attacks, including money, man power, time, and high technology. Some nation states spend a significant level of their annual gross national product on intelligence gathering.
- *FIS skills* – The FIS is highly sophisticated in human intelligence (HUMINT), signals intelligence (SIGINT), CNA, SpecOps, and electronic warfare (EW) attack techniques. For those nations that have an indigenous high technology industry, the FIS can conduct life-cycle attacks through their own industry.
- *FIS risk tolerance* – This adversary is risk averse, in that espionage is most effective when not detected. Some FIS are not above taking physical

risk by breaking and entering to steal information or leave a listening device. In addition to these traditional techniques, the modern FIS has adopted new CNA techniques to steal sensitive information from critical computer networks. However, given their preference to conceal their advanced capabilities, an FIS with sophisticated network attack techniques may not display them until absolutely necessary, instead relying on adequate, yet less sophisticated, network attack tools such as publicly available hacking and system penetration tools.

Info Warriors

The info warriors are a team of highly trained, highly motivated military professionals from a nation state's Information Warfare division, and act on behalf of the nation state in preparation or execution of a war with other nations.

- *Info warrior motivation* – The info warrior seeks to destroy the opposing critical infrastructure to reduce the effectiveness to wage war and to erode public support for the war.
- *Info warrior resources* – Since the info warrior is part of the nation state's arsenal of highly sophisticated weapons, the budget and resources for the info warrior are extremely high. During times of war, the nation state's military budget, and hence the info warrior's budget, will increase and become a national priority.
- *Info warrior skills* – Information operations conducted by nation states at war include manipulation, degradation, or destruction of data or supporting infrastructures within the targeted network. Information operations during times of crisis and war are generally conducted with full-time intelligence support from the FIS that aids in identifying network vulnerabilities, structure, and the mapping of mission-critical information about and within the targeted network. Once the information operation begins, the info warriors will use any and all means to achieve their objectives.
- *Info warrior risk tolerance* – Once in a state of war, the info warrior is willing to take extreme risks. For these reasons, the info warrior is a very formidable adversary.

Terrorist (Nonstate Actors)

This class of adversary includes organizations that engage in terrorist activities to further their political or religious goals. Terrorist organizations may cooperate with a foreign nation state, or they may be seeking visibility and publicity for specific issues or to influence social, political, or military behavior among a targeted audience.

- *Terrorists' motivation* – Terrorists seek publicity and political change by wreaking havoc, motivated by their ideology or cause. Terrorists typically resort to high-visibility destructive attacks. Currently, terrorists have not posed a significant cyber threat to critical communications and information systems. While current expert opinion believes that cyber attacks against information systems will not supplant more violent, physical (kinetic) terrorist actions, information operations attacks may be used as a force multiplier to maximize the impact of violent operations by complicating emergency responses and coordinated reactions to physical attacks. In addition, attacks on networks may disable certain physical security measures that may also increase the impact or probability of success of violent attacks. After the physical attacks occur, terrorists may target information systems to gain intelligence about planned responses or retaliation operations, and potentially attempt to disrupt the US responses to their acts of aggression. But this is speculation and currently we do not have evidence to support this.
- *Terrorists' resources* – Terrorist groups' sizes range from a few isolated and uncontrolled amateur individuals to military-structured and trained organizations. In some cases, foreign nation states sponsor terrorist groups by providing training, equipment, and political asylum.
- *Terrorists' skills* – Traditional terrorist expertise lies in making bombs as opposed to being IT or even INFOSEC specific. However, some groups have allegedly raised funds through software piracy and TV descrambler trafficking, which implies some basic hacking skills. Like other organized criminals, terrorists are likely to have basic communications interception capabilities. Some terrorist groups have embraced cellular and encryption technology to frustrate law enforcement and national intelligence gathering

efforts, and they have used the Internet to distribute propaganda regarding their organizations and objectives.

- *Terrorists' risk tolerance* – This adversary may lack high-tech capability, but they make up for it by taking extreme risks, i.e., they are willing to die to make their cause known.

Hackers

This class of adversary does not always fit into the "opposition" classification because of the diversity of hackers. A typical hacker is the recreational hacker. The danger posed by recreational hackers is that they may harm a critical computer system unintentionally. This is particularly true for the less sophisticated hackers, often referred to as *script kiddies*, who use readily available tools developed by others. Recreational hackers often engage in a form of random selection for attacking a system, choosing '.mil' and '.gov' URLs as attractive targets. Another method is to "surf" the Internet until they find an interesting location based on attention-getting characteristics such as an interesting web page found through a keyword search engine. At the other end of the spectrum is the "cracker", who is a person with the capability to penetrate an information system for malicious purposes.

- *Hackers' motivation* – Hackers conduct attacks on systems for a variety of reasons. Notoriety, thrills, and the occasional theft of service motivate the hacker. Some hackers attack computer systems simply for the challenge of penetrating an important system based on the value of the information within the network. These hackers want to match wits with the best network security experts to see how they fare. Other hackers attack information systems for the purpose of revealing vulnerabilities and weaknesses in popular software applications and hardware. Finally, crackers may attack computer systems for financial or personal gain, effectively using their skills to steal money, services, or otherwise valuable data, which they can either sell or use to blackmail their victims. The recreational hacker visits a system just because it is there or because it poses a particular challenge to the hacker's knowledge and skills.

Both hackers and crackers could be working, wittingly or unwittingly, for another class of

adversary such as the foreign nation state or terrorist organization. Some recent foreign hacker activities suggest that many hackers/crackers have some level of operational plan and may operate in concert with other hackers in mounting coordinated attacks. The 1998 attacks on the Pentagon systems known as *Solar Sunrise* is a well-known example of such an effort (http://www.sans.org/resources/idfaq/solar_sunrise.php). During periods of crisis and war, hacker activity targeting military systems tend to increase. This is probably because of the increase in awareness among the hacker community of the military mission and its presence on the Internet. During crisis and war, hackers may be using their skills to voice their opposition to the military actions by making a nuisance of themselves. But the increase in detected hacker activity during these periods is typically limited to port scans and pings, and rarely results in a security incident or causes any noticeable degradation in system functionality. Some hackers conduct useful evaluations of commercial security products and are actually beneficial to the security community. These hackers regularly test popular products looking for vulnerabilities. By publicly exposing these vulnerabilities, as opposed to secretly exploiting them on operation systems, these hackers effectively convince the product vendors to correct the vulnerabilities and improve their products.

- *Hackers' resources* – The hacker may not have much money, but will leverage technical knowledge into computing resources. Hackers often organize in underground groups, clubs, or communities, and share and exchange vulnerability data, experiences, techniques, and tools. Hackers brag about successful attacks against prestigious networks or web sites. They share detailed instructions on how to defraud service providers such as PTOs and ISPs. Hackers routinely publicize their findings through chat rooms, web sites, trade magazines, and yearly conferences.
- *Hacker's skills* – Hackers are masters of network-based attacks that have a relatively low cost of entry. Typically all they need is a personal computer and Internet access to launch their attacks. They use social engineering to steal passwords and insider information about their intended target. Although they have worldwide electronic access through the Internet, hackers

typically will not conduct attacks that require any physical access such as breaking into an office space or digging trenches to wiretap cables.

Not all hackers are as brilliant as reporters like to depict, but some of them are experts in their field and have sufficient knowledge to develop highly sophisticated tools. Once these sophisticated tools enter the public domain, less skilled hackers, so-called script kiddies, will use them indiscriminately. The alarming trend is that as the tools and attack scripts available to hackers become more sophisticated and powerful, the level of sophistication and expertise needed to run the associated attacks is dropping.

- *Hackers' risk tolerance* – Although hackers like notoriety, they do not want to get caught or detected by the law enforcement because recent offenses have resulted in severe sentences. Hackers are also very unlikely to engage in a physical attack prior to perpetrating a cyber attack: the physical risk of being discovered or killed is usually too high. Hacker attacks against classified military systems are rare because of the high physical risk involved. So far, hackers have only attempted attacks against the integrity or availability of unclassified Internet sites when the hacker believes the attack is anonymous.

Organized Crime Groups

This class of adversary includes individuals or organized criminal groups that may be either foreign or domestic. Organized crime is composed of the various national and international crime syndicates, drug cartels, and well-organized gang activities.

- *Organized crime's motivation* – The primary objective of organized criminals is to realize financial profits and establish control over markets for their exploitation. They regularly use the international financial infrastructure to launder money. Other criminals simply steal information or goods for profit or counterfeit high technology products to sell on the black market.
- *Organized crime's resources* – Organized criminals have a wide range of resources. Some criminal groups are strictly small-time with little or no budget for cyber attacks. Other groups, such as large drug cartels, are well funded and are quite experienced using computer networks to their advantage.

- *Organized crime's skills* – Criminal groups may have in-house hacking expertise, but are more likely to recruit appropriate experts in the hacking community or from among former nation state intelligence experts. Organized criminal groups use bribery, blackmail, or torture to convince cyber attack experts to work on behalf of the criminal group. As cyber attacks become more profitable, criminal groups will become more technically sophisticated.
- *Organized crime's risk tolerance* – The primary operational concerns for organized crime are to avoid interdiction, detection, and apprehension. The backbone of successful criminal operations is intelligence collection and exploitation against their intended targets and against law enforcement. Criminals generally have a low tolerance to the risk of discovery because the success of their operations depends on their ability to avoid detection and apprehension. If the risk of detection and apprehension for a particular mission is high, organized criminal groups will often use expendable low-level foot soldiers to take the risk, and hence the fall.

Economic Competitors

Economic competitors are a class of adversary that uses cyber attacks to gain an economic competitive edge in the market. Economic competitors include rival companies and even foreign governments that use national assets to foster their internal industries.

- *Economic competitor's motivation* – The primary motivation for economic competitors is to seek an economic competitive advantage through cyber attacks. This economic advantage could come from learning about a rival company's advanced research and product development before that information becomes public, or it could come from insider information about the rival company's finances or bargaining positions.
- *Economic competitor's resources* – Rival companies typically have only moderate monetary resources and they need a positive expected return on cyber attack investment. If the economic competitor has nation state sponsorship, then this class of adversary has significant resources, comparable to that nation's FIS.
- *Economic competitor's skills* – Economic competitors are fairly sophisticated in HUMINT

(recruiting insiders from their competitors), CNA, and sometimes in SpecOps through physical break-ins to steal information or technology.

- *Economic competitor's risk tolerance* – As conducting cyber attacks against rival companies could hurt the economic competitor's reputation and could perhaps lead to fines and even jail time, economic competitors typically have low risk tolerance for detection and attribution.

Malicious Insiders (Angry or Unethical Employees, Contractors, Consultants, or Vendors)

Historically, this adversary class poses the greatest threat to most critical computer systems because malicious insiders are authorized users who perform unauthorized activities with the intent to damage or steal critical resources. Insiders are particularly difficult to prepare for and defend against. Insiders include employees, contractors, consultants, product vendors, and ancillary staff such as service providers' employees and maintenance personnel. Malicious insiders may be acting on their own behalf, or they may be co-opted by another adversary class such as an FIS.

- *Malicious insider's motivation* – Motivation comes from personal gain, revenge, or ideology. Malicious insiders may have been recruited by an FIS, and thus financially rewarded by the FIS for their crimes. Others may be disgruntled employees who seek revenge against their organization for some perceived slight. Still others may have some ideological differences with the organization and seek to undermine the organization's critical missions.

In addition to malicious insiders, nonmalicious insiders also pose a threat to critical computer systems. "Attacks" from nonmalicious insiders may be the results of misuse, accidents, or other unintentional sources of harm such as the accidental insertion of malicious code from a downloaded or corrupted file. Therefore, the nonmalicious insider could be the unwitting vehicle for other classes of adversaries.

- *Malicious insider's resources* – The insider does not have or need significant resources to cause great harm to their organization. Even the most compartmented organizations must extend enough trust to employees and personnel to perform the duties for which they are assigned; therefore,

some degree of access is usually available for exploitation by an insider. Furthermore, insiders are in a position to defeat all three security services (confidentiality, integrity, and availability), and would most likely place themselves in a position where the attack is not easily attributable to themselves. While the expected number of individuals within an organization that might wish to cause harm may be low, the potential impact caused by an insider attack could be massive.

- *Malicious insider's skills* – Unlike outsiders, insiders do not need to penetrate a computer system by defeating its security mechanisms, but rather, are given access to the internal system or portions therein. For this reason, insiders do not require sophisticated attack skills. However, the most dangerous insider is the system administrator with detailed knowledge of the computer system and its security mechanisms.
- *Malicious insider's risk tolerance* – Just like any other criminal, insiders do not want to get caught and prosecuted. They will take the necessary precautions to avoid detection and attribution. However, because of their status as a trusted employee, the insider is capable of conducting attacks that are deemed too risky by other external threats. This makes insiders a valuable commodity for other adversaries such as the FIS.

Cyber Attack Space

The cyber attack space is divided into two dimensions, the time-phased attack script and the attack classes.

Time-phased attack script

A generic time-phased attack script can best be described in three main phases: (a) gain access to the system, (b) escalate privileges, and (c) execute the attack by defeating a security service and obtaining the attack objective. Each phase is comprised of one or more attack steps. Other optional attack phases include diagnosis and reconnaissance of the system and avoiding detection by covering the tracks of the attack. To protect the system, the defender needs to mitigate only one of the steps in any one of the three generic attack phases. The goal of the system designer is to find the most cost-effective way to mitigate any potential attack. The system

designer must estimate the adversary's risk tolerance and willingness to expend resources to attack the system. Of course, mitigating multiple attack steps, or mitigating a single attack step in multiple ways, provides defense in depth and more assurance against implementation flaws in the countermeasures.

Table 1 shows an example of three-phase attack that uses CNA techniques to gain access and escalate privileges, and then defeats the integrity security service by publishing fraudulent data.

Cyber attack classes

Most cyber attacks involve, at a minimum, three generic attack steps: get access to the computer system, elevate privileges, and then defeat some desired security service (i.e., confidentiality, integrity, or availability). Cyber attacks are not limited to only CNAs, but may also include attack steps from other attack classes. The following attack classes represent the tools of the trade of the cyber adversary. The attack classes form the basis of the threats that the defender must counter.

Computer Network Attacks (CNAs)

CNAs are techniques that use the computer network against itself; the network itself becomes the avenue of attack. CNA techniques include stealing, corrupting, or destroying information resident in computers and computer networks or disrupting or denying access to the computers and networks themselves. CNAs defeat vulnerabilities in applications, operating systems (O/S), protocols, and networks. Sometimes known as *hacking*, when in the hands of a well-resourced, sophisticated adversary like a nation state, CNAs are lethal weapons against modern information systems.

CNA is useful in all three of the generic attack steps. An adversary can use CNAs to gain access to

Table 1 Three-phase attack example

Three-step attack script	Attack step
Get access	Hack through firewall from Internet Send malware <i>via</i> web page
Get privilege	Gain write privileges on engineering database
Defeat security service	Alter engineering data

the information by penetrating the network perimeter defenses such as firewalls and guards. Stealthy CNAs can avoid detection by defeating or disabling the intrusion detection systems (IDS). By targeting access control and privileges management mechanisms, CNA techniques can escalate the attacker's privileges from untrusted outsider to trusted insider. Finally, CNAs can disrupt network services by flooding critical network resources, and they can defeat confidentiality and integrity by exploiting vulnerabilities in applications and operating systems.

Some examples of CNA techniques include the following:

- **Malware** – is malicious software designed to exploit a vulnerability on a computer to infiltrate the security perimeter or steal or damage the computer system resources. Examples of malware include computer viruses, worms, Trojan horses, spyware, and other malicious and unwanted software. Malware should not be confused with defective software, that is, software that has a legitimate purpose but contains harmful bugs as a result of unintentional programming errors.
- **Botnet** – is a term for a collection of software robots, or bots, which run remotely across a computer network. The bots propagate from one infected computer to another by using malware (e.g., viruses, worms, and Trojan horses) to exploit a common vulnerability on the computers. The infected computers, or bots, are remotely controlled by the bot originator, and is usually used for nefarious purposes, such as wide-scale distributed denial of service (DDoS) attacks in which all the infected computers are commanded to send oversized Internet protocol (IP) packets to a single web server.
- **Flooding** – is a specific type of denial of service (DoS) attack techniques in which the attacker demands more computer resources than are available. The flooding could occur on the network by sending too many packets or by opening too many services, or at a device level by filling up the memory or tying up the central processing unit (CPU) with computationally intensive operations.
- **Eavesdropping** – is the act of passively snooping on a computer network and collecting private or sensitive information, such as user names and passwords. Eavesdropping requires access to the computer network, which is usually obtained by

installing a sniffer on the network or by collecting the transmissions from a wireless access point.

- **Malware propagation method** – malware spreads itself, or propagates from one infected host to another, in two basic ways: a computer virus infects a piece of executable code and replicates itself onto another piece of executable code, whereas a worm is self-replicating by exploiting a common vulnerability across a computer network.
- **Attack signatures** – are typical patterns exhibited by malicious code that are used for computer IDS. A virus scanner that searches all incoming e-mail and attachments for known viruses is an example of a signature-based intrusion detection system that uses a database of known virus signatures for its pattern-matching search.
- **Polymorphic code** – is malicious code that attempts to hide from signature-based IDS by continually mutating the code while keeping the original malicious algorithm intact.
- **Stealthy attacks** – are malicious codes that attempt to hide from the defender's intrusion detection system. The most effective stealthy cyber attacks are zero-day attacks (i.e., their attack signature is not in the defender's signature database), use polymorphic code, and do not exhibit anomalous user or network behavior (i.e., does not trigger an alarm in an anomaly-based intrusion detection system).

Special Operations (SPECOPS)

SPECOPS cyber attacks are physical attacks that include “black-bag” operations, midnight breaking and entering, and physical overruns to get access to the computer systems. These attacks usually involve highly trained covert operatives and counter-intelligence agents. Some typical “black-bag” operations might include breaking into a secure area to plant a bug in the room or to install an exploit in the computer or network device. SPECOPS attacks are useful for penetrating the physical perimeter to steal information or for destroying or altering the security-critical components. Only specially trained military units (e.g., information warriors) or organized crime would carry out such high-risk operations.

Human Intelligence (HUMINT)

HUMINT is the cyber attack discipline that uses insider access to steal information or gain privileged

access to critical system resources. The world's second oldest profession, HUMINT, comprises the time-honored practice of espionage (i.e., stealing or buying information from insiders). HUMINT includes bribery, blackmail, coercion, and social engineering to co-opt an insider to do the bidding of the sponsoring adversary (e.g., nation state, terrorist, organized crime, or economic competitor). Hackers have shown a penchant for social engineering, which is fooling an unwitting insider to unintentionally violate some security policy, such as divulging his user name and password. HUMINT is a useful technique for violating the physical and cyber defensive perimeter, as well as for gaining the necessary privileges to defeat the confidentiality, integrity, and availability of the critical information residing on the computer system.

Signals Intelligence (SIGINT)

SIGINT is the cyber attack discipline that captures network communications with the objective of stealing information from the target. SIGINT is the catchall phrase that includes listening to a target's communications by either intercepting wireless transmissions or by tapping a wire or cable. SIGINT attacks will target the information system's encrypted (black) network traffic. SIGINT also includes collecting compromising electromagnetic emanations (e.g., TEMPEST emanations), performing cryptanalysis on encrypted data, and using covert channels to exfiltrate sensitive information from the unencrypted (red) side of the cryptography.

Even if the SIGINT adversary cannot break the encryption, the SIGINT adversary can still perform traffic analysis on the encrypted signal. By analyzing the source, destination, frequency, and duration of each communications session, the SIGINT adversary can derive some intelligence about the nature of the communications and its participants.

By defeating the authentication system, the SIGINT adversary can perform masquerade attacks, or man-in-the-middle attacks, in which the SIGINT adversary appears to be a legitimate user of the network by stealing or forging the necessary cryptographic authentication credentials.

Electronic Warfare (EW)

EW includes any military action involving the use of electromagnetic and directed energy to control the

electromagnetic spectrum or to destroy an enemy's sensitive electronic systems. Directed high-energy attacks can jam radio frequency (RF) links or destroy fragile electronic components. Examples of EW include high-energy radio frequency (HERF), laser, and electromagnetic pulse (EMP). These high-energy attacks target the availability of critical communications components like satellite links.

Life Cycle

Life-cycle attacks introduce exploitable vulnerabilities to a security-critical component during its design, production, distribution, or maintenance. Some critical components, like the cryptography, require a trusted development and production team to counter this life-cycle threat. Other components, such as commercial routers and firewalls, have unknown pedigrees and are, therefore, more susceptible to life-cycle attacks. Life-cycle attacks are useful techniques to introduce vulnerabilities in the network perimeter defenses and access control mechanisms, as well as to introduce a DoS Trojan horse in the critical network components (e.g., backbone routers).

Management and Control

Since most modern networks span large geographical areas, the network operators and system administrators must rely on a remote management and control (M&C) subsystem to configure and maintain the correct network functionality. Unfortunately, this distributed, remote M&C capability provides a lucrative target for the cyber adversary. The M&C subsystem is usually an afterthought for system security engineers; consequently, the M&C subsystem is often protected using inadequate defensive mechanisms. M&C attacks target vulnerabilities in this remote subsystem, resulting in the adversary having the ability to reconfigure the critical network components. M&C attacks are useful for gaining access to the system by opening up holes in the boundary protection. They are useful for granting additional privileges by reconfiguring the access control and privilege management servers. Finally, M&C attacks are useful for defeating security services like availability by erasing the network routing tables.

Table 2 shows which attack classes typically accomplish each attack phase.

Table 2 Attack class pairing with attack script phases

Attack Script Attack Class	Get Access	Elevate Privileges	Defeat Security Service
CAN			
SIGINT

Special Ops			

Cyber Risk-Management Challenges

Cyber risk management faces a few unresolved key issues, including the following:

- Independent validation of cyber risk assessment results such as adversary behavior and probabilities of successful cyber attacks.
- The need for absolute metrics for risk as opposed to the relative metrics that current cyber risk assessment processes use.
- The drive toward accurate measurements of attack probabilities derived from authentic attack data collected from operational networks.
- The need to factor low-probability/high-impact cyber attacks, for which there is no historical evidence, into the risk assessment calculations.

Data Fusion

Loosely speaking, data fusion is combining information from different sources. This is done routinely in all areas of science and engineering, though often in an *ad hoc* manner informed only by constraints and objectives of a particular analysis. The topic is ever more important as new technologies lead to new ways of collecting data, and the pervasiveness of grid computing continues to increase our ability to form virtual data sets.

Consider the following motivating example. NASA's Earth Observing System (EOS) is a constellation of Earth-orbiting satellites each of which carries a number of remote sensing instruments. These instruments collect data on the Earth's atmosphere, oceans, and land surfaces, and are intended to be used in a synergistic manner to provide a complete picture of the health of Earth's most important systems. Each instrument produces data for a multitude of variables using its own sampling and transformation algorithms to convert raw measurements into geophysical variables. Data are stored in different physical locations, in different formats, and are broken up into files according to different rules.

The logistics of finding and obtaining EOS data have led to increased interest in web services at NASA and in the science community it serves. Web services allow users to pass arguments over the Internet and invoke programs on remote computers. In particular, where large volumes of data are concerned, it often makes more sense to push analysis algorithms to the computers where data reside, than to pull data to local computers on which analysis programs are developed. A natural extension of this idea is to install components of data fusion algorithms at data repositories in such a way that a driver program could assemble and fuse data from different locations and instruments "on the fly".

Such a vision requires a unified and principled theory of data fusion specifically designed to account for and make maximum use of statistical properties of the component data sets. This article does not pretend to develop such a theory, but rather to point out that a significant portion of it already exists in several domains: survey sampling, spatial statistics (see **Global Warming; Environmental Remediation; Geographic Disease Risk**), and the study of

copulas (see **Enterprise Risk Management (ERM); Credit Risk Models; Copulas and Other Measures of Dependency**). We also discuss some of the challenges posed by data fusion for understanding and quantifying risk, and end with a short summary.

What Is Data Fusion?

The term *data fusion* means different things to different people. Related terms that may or may not mean the same thing include information fusion, sensor fusion, and image fusion, depending on the context. In all cases the terms relate to the act of combining information or data from heterogeneous sources with the intent of extracting information that would not be available from any single source in isolation. Data and sensor fusion tend to connote military applications, such as combining different forms of intelligence or different satellite images to facilitate identification and tracking of objects or entities. Image fusion has a more engineering flavor, such as reconstruction of three-dimensional objects from sets of two-dimensional views. For example, in medical imaging interest may lie in the three-dimensional morphology of tumors reconstructed from a set of two-dimensional magnetic resonance imaging (MRI) scans. In this article we focus on a more specifically statistical definition: data fusion is the act of inferring a joint distribution when one only has information about the marginal distributions.

Statistical Theory and Development

Two main lines of research lead to a statistical theory of data fusion. One emerges from the area of statistical matching: business and marketing applications in which incomplete and incongruent sample survey information is to be combined. The second arises from spatial statistical applications in which incongruent spatial sampling and different spatial support necessitate a theory for making optimal inferences from such incompatible data sources. A third area, the study of copulas, is also relevant to data fusion, and we close this section with a very brief mention of that topic.

Statistical Matching

Statistical matching [1] addresses the following problem. One has access to two independently acquired

sample survey data sets and would like to combine the information therein. Few, if any, individuals are part of both surveys, but there are some variables (survey questions) in common. The goal is to create a single data set that can be regarded as a sample from the joint distribution of all variables of interest (see Figure 1).

Statistical matching suggests the need to match individual records from the two samples, but in fact this problem is more commonly known as *record linkage* (see **Cohort Studies**). In record linkage one presumes that more or less the same individuals, or units, are present in both samples, but the mapping from one survey sample to the other is uncertain owing to transcription, recording, or other errors [1]. Not surprisingly, research and methodologies for matching and linkage have common roots and the line between them continues to be fuzzy even today [2].

Sample 1		Sample 2	
X	Z	Y	Z
x_{11}	z_{11}	y_{21}	z_{21}
x_{12}	z_{12}	y_{22}	z_{22}
$\vdots$	$\vdots$	$\vdots$	$\vdots$
x_{1N}	z_{1N}	y_{2M}	z_{2M}

Combined sample		
X	Z	Y
x_{11}	z_{11}	
	z_{21}	y_{21}
x_{12}	z_{12}	
	z_{22}	y_{22}
$\vdots$	$\vdots$	$\vdots$
x_{1N}	z_{1N}	
	z_{2M}	y_{2M}

Figure 1 Schematic view of the statistical data fusion problem in the context of statistical matching. Samples 1 and 2 record measurements on two sets of units which have few if any members in common. The combined sample results from concatenating samples 1 and 2, but results in missing values. There are a number of ways to impute the missing values with varying degrees of theoretical justification

Early statistical matching literature focuses on situations where one sample is identified as the “donor” and the other as the “recipient”. Typically, the donor is larger and more complete, but the recipient sample is of greater interest. The objective is to complete the recipient sample by inferring values on a variable that exists only in the donor, for all units in the recipient. For instance, this might be done by partitioning both samples into homogenous strata, and imputing the recipient’s missing values using regressions determined from suitable strata of the donor file. For the interested reader [1], provides a thorough history of the development and application of statistical matching theory and methods.

Regardless of what it is called, the fusion problem is also closely related to the missing data paradigm of Little and Rubin [3] (see **Repeated Measures Analyses**). Two survey samples, say with N and M units (records) respectively, can be concatenated to form a single sample of length $N + M$ in which the first N units have missing values for the variables unique to the second survey and the second M units have missing values for the variables unique to the first survey. Data fusion attempts to impute the missing data for purposes of making inferences about the underlying common population.

The framework of Little and Rubin explicitly models missingness as a random variable, which may be related to the survey variables themselves. The forms of those relationships are expressed, as with all relationships among variables, by the joint and conditional distributions of quantities of interest. Likelihood-based inference for parameters of the underlying joint distribution proceeds as usual by examining the probability of obtaining the observed sample as a function of the unknown parameters. If prior distributions are attached to the parameters, the approach is Bayesian. Missing data values are inferred from their posterior distribution, given the data. In this setting, emphasis is often placed on parameter estimation in presence of missing data rather than on data fusion *per se*.

If the primary objective is creation of a fused data set, the expectation-maximization (EM) algorithm [4] is a natural candidate for producing the desired results. EM produces maximum-likelihood estimates of unknown parameters by iteratively and alternately filling in missing data with their expected values given the observed data and the current best estimate of the parameter, and then updating

the parameter estimate to maximize the likelihood given the observed and (estimated) missing data. The EM algorithm does not necessarily converge to the global maximum of its optimization criterion, and as observed by Ressler [1], if there are no actual realizations that provide information about two variables to be fused, EM solutions may not be unique. Additional information or assumptions are required.

One way of accomplishing this is to impose prior distributions on the unknown parameters. Unfortunately, however, in the presence of missing data the computations become even messier than usual and in fact are often unsolvable analytically [1]. Markov chain Monte Carlo (MCMC) (*see Non-life Loss Reserving; Reliability Demonstration; Bayesian Statistics in Quantitative Risk Assessment*) techniques, already brought to bear for other computationally difficult Bayesian problems [5], can be used here as well. Once the posterior distributions of the missing data (given the observed data) and the unknown parameter (given the observed data) are estimated, random draws from the former can be used to fill in missing values. In fact, the principle of multiple imputation [6] uses multiple random draws to create multiple synthetic data sets in order to capture uncertainty inherent in filling in missing values. One might also simply carry the variance of the posterior distribution of the unobserved data the same way one carries and uses the variance of the presumed distribution of the observed data in further calculations on the fused data set.

To clarify and organize the data fusion framework, it is useful to introduce the following notation. Let X and Z be two random variables encoding responses from survey 1. Let Y and Z be two random variables encoding responses from survey 2. Let S_X and S_Z be indicators of nonmissingness for X and Z in the first survey, and let R_Y and R_Z be indicators of nonmissingness for Y and Z in the second survey. Finally, let $\{(X_n, Z_{1n})\}_{n=1}^N$ and $\{(Y_m, Z_{2m})\}_{m=1}^M$ be the observed samples from the two surveys respectively. Z_{1n} and Z_{2m} have the same distribution – that of Z . That is, $\{(X_n, Z_{1n})\}_{n=1}^N$ is a sample from the joint distribution of X and Z conditional on the fact that at least one of them is observed in the first survey and $\{(Y_m, Z_{2m})\}_{m=1}^M$ is a sample from the joint distribution of Y and Z conditional on the fact that at least one of them is observed in the second survey. We use the notation $[U]$ to indicate the distribution of a random variable U , and $[U|V]$ to

denote the conditional distribution of U given V . The first survey provides a sample from $[X, Z|S_X = 1 \text{ or } S_Z = 1]$. The second survey provides a sample from $[Y, Z|R_Y = 1 \text{ or } R_Z = 1]$.

If it were known, the entire joint distribution $[X, Y, Z, S_X, S_Z, R_Y, R_Z]$ could be used to obtain $[X, Y]$ by integrating out the other quantities. We only have samples corresponding to $[X, Z|S_X = 1 \text{ or } S_Z = 1]$ and $[Y, Z|R_Y = 1 \text{ or } R_Z = 1]$, so other assumptions must be made. Conditional distributions depending on $[X, S_X]$ define the bias, if any, of sample 1 relative to the unconditional distribution of X (both observed and unobserved). The same is true of $[Y, R_Y]$ for sample 2 and its relationship to Y . It is probably reasonable in most cases to assume that S_X and R_Y are independent, but it may not be reasonable to assume that S_Z and R_Z are independent depending on how the two samples were collected.

Exact and exhaustive specification of all relationships embodied in $[X, Y, Z, S_X, S_Z, R_Y, R_Z]$ depends on specific circumstances, and to the extent that future uses of the fused data set are known. However, more than one author has noted that conditional independence of X and Y on Z is required to avoid identifiability problems. Gilua *et al.* [7] provides a simple but thorough and clear discussion of this issue.

Spatial Applications

Data fusion in the context of spatial data sets has much in common with the statistical matching and missing data approaches. Both seek to impute missing values using assumptions about relationships among units and among variables. In statistical matching, the units are typically individuals – respondents in sample surveys. In spatial problems, the units might be measurement locations or individual pixels in a remote sensing image. See Figure 2.

Spatial problems highlight the notion of aggregation hierarchies: data to be fused may exist at different levels of aggregation. For instance, one may wish to fuse a data set with pixels that are 10 km^2 with one having pixels that are 17 km^2 . Moreover, the pixels may not be mutually exclusive: there may be spatial overlap and alignment issues. In other words, the units to be fused may not be congruent in the sense that discrete units (such as people) are.

These issues are known in the spatial statistics literature as change of support problems [8], but aggregation issues also exist in areas traditionally

Figure 2 General problem of data fusion in the spatial context. The units of sample 1 are the pixels in the gray grid. The units of sample 2 are pixels of the white grid. The units overlap but are of different spatial resolutions, are misaligned, and are oriented differently

under the purview of statistical matching [9]. In fact the ecological fallacy that occurs when inferences are made about individuals based on statistical aggregates is known in both spatial [10] and nonspatial [11] applications.

Kriging [12] (*see Environmental Remediation*) makes explicit use of covariances among units to impute values for unobserved ones. This is often done entirely within the context of a single data set. However, if a second data set is available that measures the same quantity, one would ideally like to fuse the two to fill in gaps and to obtain better estimates where data from more than one source are available. Or, perhaps two data sets measure different things, and interest lies in understanding their joint relationship. That is, if the two variables measure the same underlying quantity, they can be averaged in some way, and if they measure different quantities, they can be concatenated. One way around incongruent units is to krig each data set separately to a common set of locations and then fuse at each location in the same way one would had real measurements been available. Note however that the kriged field may exhibit excessive spatial dependence since the same set of observed data gives rise to kriged estimates at multiple locations. Further, optimal statistical fusion of kriged data sets may be inferior to optimal statistical fusion of the original data sets (Noel Cressie, 2007, personal communication).

Kriging deals with the change of support problem by exploiting the continuity of the underlying field and the linearity of the covariance operator. The usual spatial statistical model ([12] for example) assumes that the quantity of interest varies continuously over its domain; that is, it is a “point level” phenomenon, which varies from geographic point to point. Block kriging [12] uses the statistical characterization of point level relationships (covariances) to derive the covariance structure between “blocks” of aggregated measurements. For example, remote sensing instruments observe pixels that are spatial averages of the measured quantity over the footprint of the pixel. Since averages are linear functions, the covariances at the point level can be used to obtain covariances at the block (pixel) level.

It is interesting to consider applying the same strategy in the context of statistical matching. One might postulate a covariance function for the units based on demographic or other auxiliary variables that play the role of spatial location. If all the units represent discrete objects (e.g. people), the situation is analogous to kriging point data: predict missing response values as linear combinations of existing response values in the same data set. Then, given two imputed data sets, combine records from units that are similar with respect to the auxiliary variables by forming linear combinations of the donors. This is in fact a strategy similar to that described in [1, Chapter 2], and the same caveats expressed above for spatial data fusion apply.

The idea of common variables in statistical matching is close to that of auxiliary variables in co-kriging, followed by fusion of some sort at common locations. Missing data indicators could also be incorporated into the co-kriging framework as additional covariates to account for sampling biases. However, this is more often accomplished in spatial situations using Bayesian hierarchical models [13] that relate measurements to the true quantity of interest through an error term. The difference is that in statistical matching attention is focused primarily on the unknown joint distribution of two variables from two different samples, while in spatial applications attention is focused more on filling in missing information. If the further step of combining information from two separately kriged samples is taken, the fused data can be used to estimate characteristics of the joint distribution. Note that the latter may not be statistically

optimal because it does not bring to bear all the information available from both data sources at the initial stage.

A recent article in the *Journal of Marketing Research* by Gilula *et al.* [7] takes a significant step toward unifying the matching and spatial approaches. They use a Bayesian hierarchical model to (*see Geographic Disease Risk; Meta-Analysis in Nonclinical Risk Assessment*) "... estimate the joint distribution of the target variables directly rather than to use a matching or concatenation approach. The joint distribution can then be used to solve the inference problems It is important to emphasize that our methods are 'automatic' in the sense that they do not require modeling or in-depth analysis of the nature of the common demographics variables." Gilula *et al.* do not address the problem of incongruent units that arises in spatial applications. Their approach could be extended using Bayesian hierarchical models to cover this circumstance [12].

Copulas

Copulas are mathematical functions that link multidimensional distributions to their one-dimensional marginal distributions [14]. Briefly, if X and Y are jointly distributed random variables with joint distribution function $H(x, y)$, and marginals $F_X(x)$ and $F_Y(y)$, respectively, then $V = F_X(X) \sim U(0, 1)$ and $W = F_Y(Y) \sim U(0, 1)$ where $U(0, 1)$ indicates the uniform distribution on the unit interval. The distribution function of (V, W) is a copula:

$$\begin{aligned} C(v, w) &= P(V \leq v, W \leq w) \\ &= P(X \leq F_X^{-1}(v), Y \leq F_Y^{-1}(w)) \\ &= H(F_X^{-1}(v), F_Y^{-1}(w)) \end{aligned} \quad (1)$$

The subject is highly mathematical, and of significant importance in statistics because it provides a framework within which different forms of dependence may be studied. In principle, copulas offer an analytical solution to problems estimating unknown joint distributions when only the marginal distributions are available. The link to data fusion is self-evident.

Copulas have received plenty of attention in econometrics, finance, risk analysis, and actuarial science because of their usefulness in studying nonlinear dependence and modeling joint distributions.

At present there does not appear to be a direct connection to the data fusion literature discussed earlier in this article, but it seems clear that the motivating ideas behind copulas could offer some theoretical guidance in problems related to statistical matching and fusion.

What Challenges Does Data Fusion Pose for Risk Analysis?

Data fusion is often seen as an end in itself: the goal is the production of a data set, which is then the subject of subsequent analyses. Challenges for quantitative risk assessment arise in those analyses from the possibility that assumptions used to perform the fusion are not correct. In particular, if data fusion is performed as a preprocessing step without knowledge of the subsequent analyses, the validity of conclusions may be compromised.

In this regard, the approach based on the spatial paradigm has the advantage of providing a well-specified goal that does not depend on future use: accurate estimation of the true, underlying field. The approach also automatically provides uncertainties for those estimates.

An approach based on the statistical matching and missing data paradigms has the advantage of providing a more direct path to a fused data set without resorting to a model-based specification of the underlying field. Its disadvantage is that the resulting fused data set is more vulnerable to the assumptions used to create it precisely because it is not anchored to such a model. Moreover, conditional independence assumptions are required to avoid identifiability problems.

Perhaps the greater risk posed by data fusion is that of *not* performing it. The new classical example is failure to "connect the dots" in analysis of data from disparate sources of intelligence information (e.g., video, network, email, financial, etc.). That particular example is especially difficult because it involves different types of data. The content of this article only deals with numerical information, but clearly even greater challenges arise for multimodal data types.

Summary

We defined the objective of data fusion to be that of combining statistically heterogeneous samples to

construct a new sample that can be regarded as having come from an unobserved joint distribution of interest. The building blocks of a statistical theory of data fusion already exist in various mature areas of statistics. Elements can be found in the literature on statistical matching, missing data, and spatial statistics, and at a more theoretical level, the study of copulas. These threads need to be drawn together to provide a comprehensive framework that is internally consistent and rigorous. We hope that such a framework can provide new, quantitative methods for data fusion, and place both new and existing methods in a common frame of reference so they can be more easily compared and evaluated.

AMY J. BRAVERMAN

Decision Analysis

Decision analysis as a term could describe many methodologies that analyze the elements of a choice that is to be made and recommend a decision. However, by convention – in Anglo-American literature at least – it refers to analyses based upon the subjective expected utility model (see **Subjective Expected Utility**) of rational economic man developed during the nineteenth and early twentieth centuries in the economics literature. In parallel, the Bayesian approach to statistics (see **Bayesian Statistics in Quantitative Risk Assessment**) developed the identical model in its approach to inference and decision [1, 2]. Nonetheless, it should be recognized that there are several quite distinct approaches to decision analysis that are not covered in this article [e.g. [3–5]]. The defining characteristics of the Bayesian decision analytic approach that we describe here is that in certain respects it is explicitly subjective, modeling judgments of uncertainty and preference. Uncertainty is modeled through subjective probability (see **Subjective Probability; Interpretations of Probability**) and preference through utility functions (see **Risk Attitude; Utility Function**). In some decision analyses – though seldom have those that arise in the context of risk analyses – uncertainty is not an issue and the focus is on modeling and exploring preference, particularly in terms of balancing conflicting objectives. In such cases, preferences may be modeled through value functions (see **Value Function; Multiattribute Value Functions**) [6].

It is easy to think of decision analysis as a set of quantitative calculations that draw together subjective and objective information and so identify an “optimal” decision. However, a full understanding of decision analysis requires that one sees it as a supportive process of interactions with the decision makers through which their understanding of the external context, the choice before them, and their own judgments of uncertainty and value all evolve until the way forward becomes clear. Decision analysis may be structured around quantitative calculations, but it is the process that is key; and this process will be discussed in this article.

Bayesian Analysis

The subjective expected utility model that is central to Bayesian decision analysis is very simple. Note that we assume for the present that there is just an individual decision maker; we discuss decision analysis for groups later. One begins with underlying model of the world and the decision maker’s potential interactions with it: $c(a, \theta)$. Here $c(\cdot, \cdot)$ maps a potential *action*, $a \in A$, that the decision maker may take from a set of alternatives A to a *consequence*, $c \in C$, under the assumption that the exogenous *state of the world* may be described by some parameter $\theta \in \Theta$. Note that in principle the consequence set may be very general; but in practice the modeling process usually reduces this to an n dimensional space, where each dimension represents an *attribute* that is important to the decision maker in evaluating the options (see **Multiattribute Modeling**). The function $c(\cdot, \cdot)$, in a sense, embodies the objective aspects of the analysis, encapsulating relevant knowledge drawn from economics, engineering, environmental science, or wherever. The decision maker’s subjective judgments are encoded in two functions: a *subjective probability* distribution (see **Subjective Probability**), $P_\theta(\cdot)$, representing his or her beliefs about the actual state of the world θ and a (multiattribute) *utility* function, $u(\cdot)$, representing his or her preferences for the potential consequences. Subjective expected utility theory then ranks the alternative actions according to the increasing value of the expected utility. Thus the theory prescribes decision making by maximizing expected utility:

$$\max_{a \in A} \int_{\Theta} u(c(a, \theta)) dP_\theta \quad (1)$$

The analysis is simply connected with Bayesian statistics and forecasting because $P_\theta(\cdot)$ may be taken as the posterior distribution for θ after any available data has been analyzed [1, 7]. The basic structure Bayesian decision analysis is thus as shown in Figure 1. Also note that it is seldom the case that decisions are taken in isolation; thus the analysis may cycle through a sequence of decisions [1, 8].

There are, of course, many embellishments to this structure of decision analytic calculations. For instance, the above assumes that the alternative actions are simple entities and thus relates to a decision table model of the underlying choice (see **Decision Modeling**). Most decisions, however,

Figure 1 The structure of Bayesian decision analysis [Reproduced from [7] with permission from Springer, © 2003.]

involve contingencies, temporal relationships, and influences between the various actions and uncertainties. Thus the underlying decision model may be *decision tree* (see **Decision Trees**) or *influence diagram* (see **Influence Diagrams**). Also the analysis can give an estimate of the value of information [9]. In essence, this involves calculating the maximum expected utility without any data and the maximum expected utility if data were analyzed and the decision maker's uncertainties updated. The difference indicates the value that the data may provide the decision maker, though it is in terms of the expected utility. Thus it may be necessary to “invert” the utility function to provide a financial value of the information. There are several ways to construct upper bounds, e.g., the value of perfect information or the value of clairvoyance, on the value of information, which can be easier to calculate than the “expected maximum expected utility”, although it should be noted modern decision analytic software usually renders the fuller calculations tractable.

The Decision Analysis Process

The subjective expected utility model – at least as used within decision analysis – is a normative model, i.e., it models a conception of rational choice behavior. It is built on a set of axioms, which encapsulate or, rather, define rationality in decision making [1]. There is no pretense that the model describes actual behavior. Indeed, unguided decision making seldom fits entirely with this conception of rationality (see **Behavioral Decision Studies**). Subjective expected utility is seldom an adequate descriptive model of real behavior. Thus to use decision analysis in practice, there is a need to address the discrepancy between the rationality assumed of the decision maker and the behavior that he or she is likely to exhibit in practice. This means that the subjective expected utility model is embedded within a prescriptive process of decision support in which the decision maker is guided toward the rationality assumed within the model, mindful of the cognitive limitations and behavioral biases that he

or she is likely to exhibit in interacting with the analysis [2]. To achieve this, decision analysis broadly proceeds through the following stages.

Stage 1. *Problem formulation*

Decision problems seldom arrive fully formulated. The decision maker may be aware that a number of issues need resolving, but have little idea of what the options are or even what he or she is trying to achieve. Thus the first step is to explore the issues and concerns with the decision maker and structure a model of them. There are many creative and catalytic ways of interacting with the decision maker that can help here [10–12]. As the issues become clear, they can be structured into decision tree or influence diagram with multiattributed consequences (see **Decision Modeling; Decision Trees; Influence Diagrams; Multiattribute Value Functions**). Note that this activity does not just “build the model”, but also clarifies the decision maker’s thinking and perception of the issues that he or she faces. In knowledge management terms, it both creates and codifies knowledge [13].

Stage 2. *Elicitation*

The decision maker’s beliefs and preferences are elicited and modeled as subjective probabilities and utilities, respectively [14, 15]. This is a reflective process in which the decision maker is guided toward a consistent set of judgments that are modeled by the two functions. It is not a case of fitting functions to the decision maker’s responses to questions. There is mutual convergence; the decision maker’s self understanding and judgments may evolve as the elicitation progresses, guiding him or her toward the rationality assumed within the model.

Stage 3. *Calculation of expected utilities*

With the functions elicited, the quantitative analysis can be conducted. Bayesian methods can update the decision maker’s initial beliefs in the light of any data, the expected utilities calculated, and a ranking of the possible actions produced.

Stage 4. *Sensitivity analysis and critical evaluation*

The output of any analysis might be the spurious result of some imprecision in the inputs; so a sensitivity analysis should be always conducted. As many of the inputs in a decision analysis are based upon judgment and thus limited in their accuracy by human cognitive abilities, there is an even

stronger case for this in a decision analysis. This may be conducted by simply varying one or more input variables deterministically to see how the output ranking changes or by Monte Carlo methods (see **Uncertainty Analysis and Dependence Modeling**) [7, 16]. In fact, this fourth stage is often broadened to explore the decision analysis in many ways, e.g., varying some of the models, introducing dependencies and nonlinearities, and so on. The idea is not just to ensure that the output ranking is robust in the face of reasonable variations in the inputs and modeling assumptions, but also to help the decision maker understand the import of the analysis. Decision analysis should not simply indicate a choice of action; it should primarily aid the decision maker in understanding. It is through this understanding that the decision maker reaches the decision.

Stage 5. *Requisite?*

The final stage is for the decision maker to judge whether the analysis is a requisite for his or her purposes [1, 2, 17]. Has it brought him or her enough confidence to go ahead and decide; or are there still aspects of the situation that he or she feels are unmodeled and which, if included in the analysis, might lead to a different conclusion. In the former case, the analysis stops and the decision maker decides. In the latter case, the analysis cycles returning to an earlier stage and exploring a more sophisticated model.

This description of the decision analytic process is necessarily simplistic. The stages may not be clearly delineated nor the operations confined to a single stage. For instance, French [7] argues that sensitivity analysis should permeate all stages, driving the modeling and shaping of the elicitation procedures, in addition to evaluating the robustness of the conclusions. It should also be mentioned that if the decision maker rejects the guidance of the process, as he or she might, if in the elicitation process he or she cannot provide responses consistent with the underlying Bayesian model, then this form of decision analysis is not for them. Other approaches, such as [3–5] mentioned above, may be more suited to them, though a Bayesian might find them irrational.

Group versus Individual Decision Analysis

The subjective expected utility model is essentially a model of the decision making of a rational individual. It does not apply to groups. Indeed, Arrow

has shown that in effect ideals of rationality and ideals of democracy are in conflict (*see Group Decision*) [1, 18]. On reflection this is not too surprising; decision making requires an expression of will and free will resides in individuals, and not in groups. Groups should be seen as social processes, which translate the decisions of the individual members into an implemented action [18, 19]. In such circumstances, the role of decision analysis is extended so that it does support not only the growth of each group member's understanding, but also supports communication between group members and the growth of shared understanding and – hopefully – consensus. Thus the decision analytic process described in the previous section needs to be embedded in a more discursive and deliberative process within the group, for instance, as in a decision conference or facilitated workshop for a small group (*see Decision Conferencing/Facilitated Workshops*) or a public participation process for larger groups (*see Public Participation*).

It should be recognized that not everybody who takes part in a decision analysis is a decision maker (*see Players in a Decision*). For instance, the decision makers may seek advice of experts; indeed, in very many contexts they would be exceedingly wise to do so. In such cases, the experts provide the subjective probability modeling of uncertainty or at least have a substantial input into this. The incorporation of expert judgment into the elicitation and modeling process requires some subtlety (*see Expert Judgment*) [20]. Similarly, the decision makers may identify a number of stakeholders whose views they may wish to take into account in the preference modeling. Thus the elicitation of the (multiattribute) utility function may reflect the judgments of stakeholders who are not decision makers themselves (*see Supra Decision Maker*).

Discussion

We noted in the introduction that there are other schools of decision analysis. Why do we promote the one described here? There are many reasons. French and Rios Insua [1] argue for the validity of this approach on six grounds:

- it has an axiomatic base that encodes persuasive tenets of rationality;
- there is a lack of counterexamples, which might cause one to question the analysis;
- it is feasible – the calculations are, by and large, straightforward, given modern algorithms and software;
- sensitivity and robustness analyses allow one to explore the interplay between the objective and subjective inputs and their effect on the conclusions;
- with modern graphical methods, it is transparent to users, bringing them understanding and not just a quantitative prescription;
- it is compatible with many worldviews and philosophies, i.e., it can be tailored to the perceptions of the decision makers.

In addition, we may note in the context of this encyclopedia that with its emphasis on modeling uncertainty with probability, decision analysis coheres with the general approach of risk analysis. Indeed, in many respects the literatures of decision and risk analysis are virtually indistinguishable. Perhaps decision analysis is more even handed in treating uncertainty and value with risk analysis, placing more emphasis on uncertainty modeling, but the underlying principles are to all intents identical.

Decision Conferencing/Facilitated Workshops

Decision conferencing provides a structured group approach for assessing the risks associated with several options, with expert judgment (*see* **Expert Judgment**) providing some or all of the inputs and models based on decision theory used to combine the inputs into an overall assessment. A facilitated workshop brings together experts about a specific risk criterion, with an impartial facilitator taking the group through the process of discussing the meaning of each criterion, establishing a measurement scales, and appraising options on the scales. At a subsequent decision conference including the key players, the facilitator guides participants through the process of making the final judgments about inputs and trade-offs between criteria that allow the decision theory model to bring together all the inputs to provide an overall ordering of the options.

The primary reason for working with groups of experts and key players is to benefit from their collective experience, knowledge, and wisdom [1]. Face-to-face debate and deliberation circumvents risk assessments that are anchored in one expert's experience, and generate consensus assessments that are different from the averages of individual expert's judgments [2]. In addition, the group-generated assessments carry an authority that is greater than a risk assessment given by just one individual, and participants are committed to the group's product. It is the modeling and group discussion, rather than a watered-down compromise, that makes it possible for the group to achieve a position that often represents a new perspective on the risk issues (*see* **Group Decision**).

In the sections to follow, the workings of a decision conference and its stages, the role of the facilitator, the use of special group decision support rooms, benefits of decision conferencing, why they work, a brief history, when decision conferencing is appropriate, and guidelines for their use are explained. A case study then shows how facilitated workshops and decision conferences enabled the United Kingdom's Committee on Radioactive Waste Management to engage in a public consultation and risk assessment

exercise that led to formulating and recommending 15 policies that were accepted by the Secretary of State for the Environment.

The Decision Conferencing Process

Decision conferencing is a series of intensive working meetings, called *decision conferences*, attended by groups of people who are concerned about some complex issues facing their organization [3]. There are no prepared presentations or fixed agenda; the meetings are conducted as live, working sessions lasting from 1 to 3 days. A unique feature is the creation, on the spot, of a computer-based model that incorporates data and the judgments of the participants in the groups. The model is often based on multicriteria decision analysis (MCDA) [4] (*see* **Multiaattribute Modeling**), which provides ample scope for representing both the many conflicting objectives expressed by participants and the inevitable uncertainty about future consequences. MCDA models are particularly useful for showing how costs, risks, and benefits can be balanced in selecting the best options. The model is a "tool for thinking", enabling participants to see the logical consequences of differing viewpoints and to develop higher-level perspectives on the issues. By examining the implications of the model, then changing it, and trying out different assumptions, participants develop a shared understanding and reach agreement about the way forward.

Stages in a Typical Decision Conference

Four stages typify most decision conferences, though every event is different. The first phase is a broad exploration of the issues. In the second stage, a model of the participants' judgments about the issues is constructed, incorporating available data. All key perspectives are included in the model, which is continuously projected so that all participants can oversee every aspect of creating the model. In the third stage, the model combines these perspectives, reveals the collective consequences of individual views, and provides a basis for extensive exploration of the model, which is always done on-line. Discrepancies between model results and members' judgments are examined, causing new intuitions to emerge, new insights to be generated, and new perspectives to be revealed. Revisions are made and further discrepancies explored; after several iterations, the new results

and changed intuitions are more in harmony. Then the group moves on to the fourth stage summarizing key issues and conclusions, formulating next steps and, if desired, agreeing on an action plan or a set of recommendations. The facilitator prepares a report of the event's products after the meeting and circulates it to all participants. A follow-through meeting is often held to deal with afterthoughts, additional data, and new ideas.

Role of the Facilitators

The group is aided by one or two facilitators from outside the organization who are experienced in working with groups. The main tasks of the facilitators are to see and understand the group life, and to intervene, when appropriate, to help the group deal with the current issues and maintain a task orientation to its work. The facilitators attend to the processes occurring in the group and provide structure for the group's tasks, but refrain from contributing to content. They structure the discussions, helping participants to identify the issues and think creatively and imaginatively. The facilitators help participants in *how* to think about the issues without suggesting *what* to think [5]. By refraining from contributing to the content of discussions, the facilitators maintain their impartiality, which is not always an easy task, especially when they are knowledgeable about the content. In those cases, it is best to use that specialist knowledge to frame questions to the group, rather than providing answers. The facilitator acts as a process consultant, always trying to be helpful, mindful that it is the client who owns the problem and the solution and that everything the facilitator does is an intervention. These three principles are just 3 of the 10 process consultancy principles described by Schein [6].

A key function of the facilitators is to help the group deal with the anxiety that inevitably accompanies group work: the group establishes a life that is not always congruent with the lives of the individuals in the group. A covert "basic assumption" develops: work beneath the surface that hinders accomplishment of the overt task. To date, research has identified five basic assumptions: fighting with each other or the facilitator, pairing of two people who the group expects will protect the group's security, becoming dependent on an individual in the group or on the facilitator to "save" the group, developing an intense

sense of belongingness, and acting as if the individual is the only reality [7, 8]. This is an aspect of the complex workings of groups, explored for many decades at the Tavistock Institute of Human Relations, and the subject of an anthology reporting the research findings of explorations in experiential groups [9].

Group Decision Support Rooms

For a group to work effectively, participants require an environment that is conducive to problem solving. Two basic principles help to ensure lively interaction:

1. all participants should be in direct eye-to-eye contact with each other; and
2. participants should be able to see and read all displays, flip charts, projection screens, and other visual aids.

Most work rooms are equipped with rectangular tables, often arranged in a [] shape. This arrangement provides direct eye contact from one side to the other, with those seated at the top table able to see everyone, but participants lined up on the sides unable to see through each other. Conversations are often directed from one side of the table to the other, less often along the same side, and frequently from the top. A better arrangement is more circular: $\cap$ shape, with an opening at the front to create a space for projecting the output of a computer.

Cabaret style, shown in Figure 1, provides an effective arrangement: several circular tables each seating four to six people. By slightly staggering the tables it becomes possible for the person talking to be seen by anyone, with just a slight shift in body position. In addition, this arrangement provides opportunities for the facilitator to give the same task to each table, with participants working on the task briefly and then reporting back to the whole group. In this way, differences within each group are worked on, often to consensus, with new differences appearing after each group reports back, which are then to be worked on by the whole group. In this way, the cabaret-style seating encourages everyone at a table to participate, everyone gets a chance to have their say, and all perspectives are fairly aired. Groups are often surprised by the diversity of opinion that is revealed, leading participants to realize that their own views are more anchored in their past experience than they had appreciated, leading them to

Figure 1 Cabaret-style room layout for a decision conference

become more receptive to alternative points of view. A useful discussion of room arrangements is given by Hickling [10].

Benefits of Decision Conferencing

The marriage in decision conferencing of information technology, group processes, and modeling of issues provides value-added to a meeting that is more than the sum of its parts. Follow-up studies, conducted by the Decision Analysis Unit at the London School of Economics and by the Decision Techtronics Group at the State University of New York, of decision conferences in the United Kingdom and the United States, for organizations in both the private and public sectors, consistently show higher ratings from participants for decision conferences than for traditional meetings [11, 12]. Organizations using decision conferencing report that the process helps them to arrive at better and more acceptable solutions than can be achieved using usual procedures, and agreement is reached more quickly. Many decision conferences have broken through stalemates created previously by lack of consensus, by the complexity of the problem, by vagueness and conflict of objectives, by ownership

in “fiefdoms”, and by failure to think creatively and afresh about the issues.

Why Decision Conferencing Works?

Decision conferencing is effective for several reasons. First, participants are selected to represent all key perspectives on the issues, so agreed actions are unlikely to be stopped by someone else arguing that the group failed to consider a major factor. Second, with no fixed agenda or prepared presentations, the meeting becomes “live”, the group works in the “here and now”, and participants get to grips with the real issues that help to build consensus about the way forward. Third, the model plays a crucial role in generating commitment. All model inputs are generated by the participants and nothing is imposed, so the final model is the creation of the group and is thereby owned by participants. Perhaps most important, the model helps to minimize the threat to individuality posed by the group life: the model reveals higher-level perspectives that can resolve differences in individual views, and through sensitivity analysis shows agreement about the way forward in spite of differences of opinion about details. Fourth, computer modeling helps to take the heat out of disagreements. The model allows participants to try different judgments without commitment, to see the results, and then to change their views. Instant play back of results that can be seen by all participants helps to generate new perspectives and to stimulate new insights about the issues. Wishy-washy compromises are avoided.

A Brief History of Decision Conferencing

Decision conferencing was developed in the late 1970s by Dr. Cameron Peterson and his colleagues at Decisions and Designs, Inc., largely as a response to the difficulty in conducting a single decision analysis for a problem with multiple stakeholders, each of whom takes a different perspective on the issues. The approach was taken up in 1981 at the London School of Economics and Political Science (LSE’s) Decision Analysis Unit by Dr. Larry Phillips, who integrated into the facilitator’s role many of the findings about groups from work at the Tavistock Institute of Human Relations. The service and supporting software continued to be developed throughout the 1980s and 1990s at the LSE in association with International Computers Limited and Krysalis Limited, and now

in the 2000s through Catalyze Limited. As decision conferencing spread around the globe, facilitators felt a need to share experiences, so they created the International Decision Conferencing Forum, which meets annually. Decision conferencing is now offered by about 20 organizations located in the United Kingdom, the United States, Portugal, Australia, New Zealand, and Hungary.

When Decision Conferencing is Appropriate

Decision conferencing can be applied to most major issues facing private organizations, government departments, charities, and voluntary organizations. Topics typically cover operations, planning, or strategy. Risk assessment forms a part of nearly every decision conference, for the generic issue facing all organizations is how best to balance costs, benefits, and risks. Risk is a component in all these decision conference topics: to evaluate alternative visions for the future; to prioritize R&D projects and create added value; to design factories, ships, and computer systems; to resolve conflict between groups; to allocate limited resources across budget categories; to evaluate the effectiveness of government policies, schemes, and projects; to improve utilization of existing buildings and plant; to determine the most effective use of an advertising budget; to assess alternative sites for a technological development; to deal with a crisis imposed by potentially damaging claims in a professional journal; to develop a strategy to respond to a new government initiative; and to create a new policy for health care provision. Any issue that would benefit from a meeting of minds in the organization can be effectively resolved with decision conferencing, which provides a way for “many heads to be better than one”.

Guidelines

Experience shows that decision conferencing works best in organizations when four conditions are met reasonably well. First, the style of decision making in the organization should allow for consultation and deliberation, provided there is adequate time to do so. Second, the organization should be open to change, for decision conferencing is usually experienced as a very different way to deal with complex issues. Third, a climate of problem solving should exist, so that options can be freely explored. Finally, authority and

accountability should be well distributed throughout the organization, and should be neither concentrated at the top nor totally distributed toward the bottom. When these conditions are met, decision conferencing can release the creative potential of groups in ways that enable both the individual and the organization to benefit.

A Case Study

After effectively ignoring the issue of what to do with the accumulating radioactive waste in the United Kingdom, the UK government created the Committee on Radioactive Waste Management (CoRWM) in November 2003. This committee was asked to start with a blank slate, consider all possible policies for managing the UK’s radioactive waste, and recommend by July 2006 on what should be done. But in doing so, they were to work openly with full transparency, to be inclusive, and to make recommendations that inspire public confidence.

From the spring of 2005, this author and colleagues facilitated many workshops with groups of experts who assessed value scores of the options on more than two dozen criteria comprising an MCDA model. A final decision conference with the CoRWM members at the end of March 2006 elicited criterion weights, and many sensitivity analyses looked at how overall weighted preference scores might change with different input assumptions about scores and weights. The model proved to be remarkably robust, with the deep disposal options consistently coming out as more preferred than the temporary storage options. Subsequently, CoRWM formulated 15 recommendations, which were passed on to the government in July 2006. In November 2006 the government accepted the key elements of CoRWM’s recommendations, and work is now ongoing to select a site. Hardly any criticism of this work has appeared in the media, which is a tribute to the openness with which CoRWM conducted their work. The following sections describe this case study in more detail.

The Initial Work

CoRWM members were chosen by the Department of the Environment, Food, and Rural Affairs (DEFRA) from over 200 applications. The committee represented great diversity of perspectives on the

Figure 2 Value tree for the radioactive waste case

issue of radioactive waste disposal, from enthusiastic nuclear supporter to Greenpeace skeptic. The committee first established a methodology, analytic-deliberative discourse [13], which relies on both holistic assessment and analytic modeling of values.

Then they set to work engaging the public in eliciting the views of citizens and stakeholders from different cross sections of society about the options for managing the wastes. Eventually, 14 viable options were grouped in three categories: interim storage,

geological disposal, and nongeological disposal, the latter two assumed to be permanent disposal categories.

CoRWM then identified 10 objectives, which they called *headline criteria*, which should be met as far as possible by an option. Criteria under those headline criteria provided practical realizations of the objectives, enabling the options to be scored meaningfully. Figure 2 shows the completed MCDA value tree. Note that the word “risk” does not appear; the many impact subcriteria effectively cover all aspects of the risk of managing radioactive waste, but using terms that can be defined with sufficient clarity so that the options can be scored on the subcriteria.

The Workshops

The committee selected specialists who attended several facilitated workshops in 2005 to clarify definitions of the criteria and to establish equal-interval assessment scales. An example of a scale is shown in Table 1.

The nine-point scale was constructed by first asking the experts to define a minimally acceptable definition of “1” and a maximally feasible definition of “9” such that all options would fall within the range from 1 to 9. The next step defined point “5” such that the value difference between 1 and

5 was the same as between 5 and 9. For this and many other scales, further definitions for points 3 and 7 were defined so as to provide equal value increments as well. Thus, this process effectively defined value functions by incorporating them into the measurement scale, effectively a Likert scale [14].

The expert workshops resulted in many changes to the definitions of the criteria, including the merging of two criteria that were deemed as not mutually preference independent (Costs and Effort, under the headline criterion “Burden on future generations”). Much discussion and debate attended the formulation of nearly every subcriterion, as the different experiences of the experts were revealed and their conflicting perspectives aired, eventually leading to agreement about how the subcriterion should be defined.

In later workshops, the same experts scored the options on the subcriteria. The process of committing to a number between 1 and 9 led to further discoveries of differences in viewpoint, and the ensuing discussion attempted to resolve those differences to arrive at a consensus score. When consensus could not be reached, the median value was input to the computer model, with the range noted and later subjected to sensitivity analysis.

In the meantime, CoRWM engaged the public in scoring and also in swing weighting the scales (*see Multiattribute Modeling*). The latter was a process

Table 1 The Flexibility subcriterion for the radioactive waste case, showing the nine-point scale for scoring the options

Subcriterion 28: Flexibility	
Extent to which the option is expected to allow for future choice and respond to unforeseen or changed circumstances over the 300-year time span	
9	System is fully monitored and adaptable, and the waste is easily retrievable using the existing system
8	
7	Key system elements can be monitored and are moderately adaptable, and the waste retrieval requires some modification of the system
6	
5	Some system elements can be monitored, adaptability is limited, and waste retrieval is moderately difficult
4	
3	Few system elements are monitored, little adaptability in the system, and it is difficult to retrieve the waste
2	
1	Monitoring options is severely restricted, the system is not adaptable, and waste retrieval is very difficult

Figure 3 Final result for the impacts criterion in the radioactive waste case. The six left bars are for storage options and the three right bars are for disposal options

that compared the swings in value from 1 to 9 on one scale as compared to another. One CoRWM member summarized the views of citizens and stakeholders about scoring and weighting, and these views were subsequently used in sensitivity analyses.

The Final Decision Conference

At the end of March 2006, a final decision conference with CoRWM members provided the opportunity to complete the MCDA model by weighting the criteria. The cabaret-style seating placed the members at two tables, with weights discussed separately at the tables. Each group reported its views and a whole-group discussion followed, usually to consensus. When consensus could not be reached, recording the extreme views left them to be tested in sensitivity analyses.

Figure 3 shows the final result for the high-level wastes, the most dangerous waste stream, for the nine options relevant to that waste stream. Only the impacts criteria are shown, with the stacked bar graph

displaying the contribution of each headline criterion, and the numbers at the right giving the relative weights associated with each headline criterion. It is clear that the three geological disposal options score higher, overall, than the six storage options. Subsequent sensitivity analysis rarely changed this picture. Substituting optimistic scores for the storage options and pessimistic scores for the disposal options on all criteria for which the experts could not agree about the scores very slightly reduced the difference between the storage and disposal options, but the relative heights of the bar graphs remained unchanged. Testing the robustness of this result against differences of opinion among the CoRWM members' judgments about weights did not change the picture. Nor did it shift when scores and weights representing different views of citizens and stakeholders were tested in the model. Overall, a remarkably robust result emerged.

A week later, the CoRWM committee met again to engage in a holistic analysis, which largely confirmed the results of the MCDA. Taking these appraisals

into account, along with deep consideration of ethical issues, the committee then set about drafting its recommendations, which were made available to the public for comment. By July 2006 a final set of 15 recommendations was forwarded to the government. These revolved around three main themes: geological disposal as the end state, improved interim storage, and a new approach to implementation that engages local communities to participate willingly. In November the Secretary of State, David Miliband, accepted the suggested policies. The Implementation Planning Group, established by DEFRA, is now taking the lead on the next steps. CoRWM's work was conducted in full public view, with all reports archived at that time on <http://www.corwm.org.uk>, now a valuable resource for all aspects of this project. A major conclusion from this project is that analytic-deliberative discourse methods, like those embodied in decision conferencing, can be made to work on important risk assessment projects.

Decision Modeling

In its simplest form, Bayesian decision modeling can be formulated as follows: a decision maker (DM) needs to choose a single action $a \in A$ where A is the set of acts – called the *action space* – she has available. The consequence $c(a, \theta)$ of this choice a will depend on the state of nature $\theta \in \Theta$ where Θ – called the *state space* – is the set of all such states the DM believes might happen. When both $A = \{a_1, a_2, \dots, a_m\}$ and $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ are finite sets, the consequences $\{c(a_i, \theta_j) = c_{ij} : i = 1, 2, \dots, m, j = 1, 2, \dots, n\}$ can be expressed as a table called a *decision table* as shown in Table 1.

Such tables need not be algebraic. Ideally, the acts, the states of nature, and the consequences are all given in common language and in simple problems can be elicited directly from the DM's verbal description of her problem.

Example 1 There is a suggestion that an infection has entered a herd of cattle. If it has, then there is a small possibility that the infection may be detected entering the food chain. The authorities could choose to continue to observe the herd, but otherwise do nothing, or order the immediate culling of the herd. This problem could be represented by the decision table (Table 2).

Here, the consequence c_{11} , to the authorities, is the cost of the observation. Consequence c_{12} is the cost of the observation but also, given that the infection

enters the food chain, the cost incurred by the mass withdrawal of foodstuff from the market and the costs to farmers associated with the fear of beef products and the consequent loss of jobs in the industry. Consequences c_{21} and c_{22} are the same and consist of the cost of the cull and the costs to all farmers associated with a loss of confidence in beef products, albeit after any health risk has been demonstrably swiftly addressed.

The example above illustrates several points. First, while decision modeling, it is necessary to be clear *whose* consequences we are considering. We need to consider the consequences for those in charge (owners or their agents) of the decisive act. In the problem above, the authorities are the owners of the act – (not the farmer of the possibly infected cattle or beef farmers, in general). Second, a decision has to be made as to the precise lists of legitimate attributes of the consequences. Note, in our example, we have omitted any explicit evaluation of health risk. If health risks might endure after a mass withdrawal of foodstuffs, such an evaluation would normally need to be included in any decision analysis. Third, as far as possible the state space should contain events that are eventually resolved. Thus, whether the infection is detected as entering the food chain is resolvable, although, whether it actually entered may not be. Considerable effort often needs to be expended to define states in sufficient detail and clarity so that they are resolvable (see [1, 2]). In particular, states need to be defined in sufficient detail so that the consequences arising from the state and each possible act are clear (see [2] for further discussion of this issue).

Fourth, the separation of acts and states of nature is useful in the sense that it often helps the DM to discover acts she had not previously considered. In the example above, these might include a partial cull of the herd. This augmentation of the problem often necessitates new states being added. The description thus dynamically evolves until the DM believes that it represents her problem satisfactorily, or is *requisite* (see [3]). Using semantics that allow the DM to develop her description so that it faithfully represents what she believes is the structure of her problem, without getting into early quantification, is an essential aspect of a decision analysis. The decision table is the simplest such framework. More expressive alternative frameworks are the decision

Table 1 A decision table

	States of nature						
	θ_1	θ_2	$\dots$	θ_j	$\dots$	θ_n	
Actions	a_1	c_{11}	c_{12}	$\dots$	c_{1j}	$\dots$	c_{1n}
	a_2	c_{21}	c_{22}		c_{2j}		c_{2n}
	$\vdots$			$\ddots$			$\vdots$
	a_i	c_{i1}	c_{i2}		c_{ij}		c_{in}
	$\vdots$					$\ddots$	$\vdots$
	a_m	c_{m1}	c_{m2}	$\dots$	c_{mj}	$\dots$	c_{mn}

Observe	c_{11}	c_{12}
Cull herd	c_{21}	c_{22}

tree (see **Decision Trees**) and the influence diagram (see **Influence Diagrams**), see below.

Probabilistic Uncertainty and Optimal Decisions

The value of the state of nature θ is usually at best only partially known to the DM when she needs to act. However, being a Bayesian she is willing to articulate her beliefs about the states of nature probabilistically: by a density (or if Θ is discrete, a probability mass function) $p(\theta)$ called her *prior density* (mass function). For each consequence $c \in C$, she will assign a score $u(c)$ – called her *utility score* for c . The utility score will assign a numerical value that reflects how good, in her own eyes, a consequence is. Thus, in particular, if she thinks that consequence c_2 is at least as preferable as a consequence c_1 then her utility score $u(c_2) \geq u(c_1)$. It is common to assign a value zero to the utility of the worst consequence and a value one to the most desirable consequence, although this is not formally necessary. How the real-valued utility function is formally defined and elicited is discussed elsewhere (see **Utility Function**).

Because the state of nature is typically not fully known when the act needs to be chosen, it is often not immediately clear which act is the best choice. An act that is good in one state of nature may not be good in another. Bayesian decision theory states that for a DM to be rational (in a sense defined in e.g. [1, 4–6]), she should choose an act $a^* \in A$, her space of possible actions, so that a^* – often called her *Bayes decision* – maximizes her expected utility $\bar{u}(a)$ on the set A , i.e.,

$$a^* = \arg \max \bar{u}(a) \quad (1)$$

When θ is discrete and takes only a countable set of values, $\bar{u}(a)$ can be written as

$$\bar{u}(a) = \sum_{\theta \in \Theta} u(c(a, \theta)) p(\theta) \quad (2)$$

while when θ has an absolutely continuous density $p(\theta)$

$$\bar{u}(a) = \int_{\theta \in \Theta} u(c(a, \theta)) p(\theta) d\theta \quad (3)$$

When the axioms that logically lead the DM to a Bayes decision are violated, it can be demonstrated that there will always be scenarios where the DM's preferences over acts are inconsistent (see e.g., [7]). So, there are strong arguments for encouraging the

DM to choose an act to maximize her expected utility. However, it is also true that DMs often exhibit preferences that are not expected utility maximizing. Indeed, there is even evidence to suggest that without coaxing, it is common for DMs not to think in terms of actions, states of nature, and their consequences at all (see, for example [8])! So this Bayesian decision methodology is not primarily descriptive, but prescriptive. The main use of Bayesian decision analysis is to encourage a DM to make wise choices and choose explicable acts in the face of uncertainty (see e.g., [7]).

Using Data to Guide Decisions

On many occasions, it is possible to arrange to take measurements $\mathbf{x} \in \mathbb{X}$ of a random vector $\mathbf{X}$; often at a cost in money or resources. For example, in the risk scenario described above, it might be possible to sample the herd and check this sample for any signs of the infection. Our choices are then whether to exploit this opportunity to sample, if so, which measurements to take, and given that we take measurements, to decide how best to act in the light of them. In particular, we need to help the DM choose a *decision rule* $d(\mathbf{x}) \in \mathbb{D}$ that specifies the act $a \in A$ she takes as a function of the measurements $\mathbf{x} \in \mathbb{X}$. Again Bayesian decision theory prescribes that the DM should choose a *Bayes decision rule* $d^*(\mathbf{X})$ where

$$d^*(\mathbf{X}) = \arg \max \bar{u}(d(\mathbf{X})) \quad (4)$$

and where, when $(\mathbf{x}, \theta)$ are discrete,

$$\bar{u}(d(\mathbf{X})) = \sum_{\mathbf{x} \in \mathbb{X}} \left\{ \sum_{\theta \in \Theta} u(c(d(\mathbf{x}), \theta)) p(\theta | \mathbf{x}) \right\} p(\mathbf{x}) \quad (5)$$

while when $(\mathbf{x}, \theta)$ has an absolutely continuous density $p(\mathbf{x}, \theta)$,

$$\bar{u}(d(\mathbf{X})) = \int_{\mathbf{x} \in \mathbb{X}} \left\{ \int_{\theta \in \Theta} u(c(d(\mathbf{x}), \theta)) p(\theta | \mathbf{x}) d\theta \right\} \times p(\mathbf{x}) d\mathbf{x} \quad (6)$$

Here $p(\theta | \mathbf{x})$ – the posterior mass function or density – is usually calculated using Bayes Rule

$$p(\theta | \mathbf{x}) = \frac{p(\mathbf{x} | \theta) p(\theta)}{p(\mathbf{x})} \quad (7)$$

where $p(\theta)$ is the DM's prior mass function or density, capturing her beliefs before seeing the resulting

measurement $\mathbf{x}$, $p(\mathbf{x}|\theta)$ specifies her probability of learning that $X = \mathbf{x}$ when the state of nature is θ , and

$$p(\mathbf{x}) = \sum_{\theta \in \Theta} p(\mathbf{x}|\theta)p(\theta) \quad (8)$$

when $(\mathbf{x}, \theta)$ is discrete and

$$p(\mathbf{x}) = \int_{\theta \in \Theta} p(\mathbf{x}|\theta)p(\theta) d\theta \quad (9)$$

when $(\mathbf{x}, \theta)$ is absolutely continuous. It is simple to check that in regular cases, for example, when the spaces $\mathbb{X}$ and Θ are both finite and $p(\mathbf{x}, \theta) > 0$ for all $\mathbf{x} \in \mathbb{X}$ and $\theta \in \Theta$ that for each $\mathbf{x} \in \mathbb{X}$, the DM should choose d so that $d(\mathbf{x})$ maximizes.

$$\bar{u}(d(\mathbf{x})) = \sum_{\theta \in \Theta} u(c(d(\mathbf{x}), \theta))p(\theta|\mathbf{x}) \quad (10)$$

When for any $\mathbf{x} \in \mathbb{X}$, θ is absolutely continuous with a density $p(\theta|\mathbf{x})$ then $\bar{u}(d(\mathbf{x}))$ is given by

$$\bar{u}(d(\mathbf{x})) = \int_{\theta \in \Theta} u(c(d(\mathbf{x}), \theta))p(\theta|\mathbf{x}) d\theta \quad (11)$$

and the decision rule $d(\mathbf{x})$ which maximizes this for each $\mathbf{x} \in \mathbb{X}$ is also a Bayes decision rule. Thus (in such regular cases), the DM should plan to choose an act that maximizes her posterior expected utility for each possible value $\mathbf{x} \in \mathbb{X}$ she might observe.

Issues and Developments

This formulation of Bayesian decision theory follows most closely the approach taken by Savage [4] who separated out the action space and state space as described above. This works very well for simple decision problems, but the semantics of the decision table are restrictive. Not all decisions may be possible or sensible, given certain states of nature and states are often impossible, given a certain action is taken. For example, in the setting described above, inoculating the herd after it is culled would be absurd. Furthermore, learning that the herd are all dead makes culling it impossible. This can make the decision table at best ambiguous and difficult to explain. Furthermore, decisions are often taken sequentially, where each new act provides new information about the states of nature. Thus, in the example above, we might choose a decision rule that first uses a crude test for the presence of the infection and on the basis of the results of this test, a more precise but costly test may be used. In these sorts of scenario,

the decision table is again not the best framework for representing the broad structure of such a decision problem. Finally, if we have a continuous state space, then the decision table can no longer be used to summarize the structure of the problem, while other frameworks, such as the influence diagram can. For all these reasons, various alternative representations of decision problems have been developed; two of the more popular and established representations are the decision tree (see **Decision Trees**) and the influence diagram (see **Influence Diagrams**).

Decision Trees

Although it is one of the oldest representations of a decision problem, the decision tree is a very versatile and general framework within which one can calculate and provide an explanation for a Bayes decision rule in a given decision problem (see **Decision Modeling**). It is possible to modify the representation so that it represents decision problems with continuous variables, but it is most expressive and useful when both the state space and the decision space are finite: the only case we consider here. Unlike many of its competitors – like the influence diagram (see **Influence Diagrams**) – it is flexible and expressive enough to represent asymmetries within both the decision space and outcome space explicitly through its topology. Of course, this flexibility can also be a drawback. Because the complete set of possible unfoldings of situations is expressed explicitly, the decision tree can be topologically complicated even for relatively simple problems. Nevertheless, the framework it provides is still extremely valuable.

The decision tree represents a problem sequentially, encoding step by step which options are open to the decision maker (DM) at a given time, and how the situation the DM might find himself or herself in could develop. So decision trees are particularly powerful in scenarios where each decision rule $d(\mathbf{x})$ is naturally specified as an ordered *decision sequence* $d(\mathbf{x}) = (d_1, d_2, \dots, d_k)$ where new information, pertinent to the states of nature, is gathered between the component decisions $d_i, i = 1, 2, \dots, k$: see the example below.

Once the tree coding how information is acquired through different decisions is elicited, the topology of the tree can be supplemented with probabilities and utilities, and this information utilized to calculate a Bayes decision rule. So the decision tree gives not only an evocative and explicit representation of important *qualitative* features of a decision problem, like the possible unfoldings, the relative timing of decisions, and the possible acquisition of new information in the light of each component decision, but can also be used as a formal framework for calculating the best course of action in the light of the *quantitative* information provided by the DM. We illustrate this process below.

It should be noted that a decision problem has many decision tree representations, with different

trees having different purposes. There are three types of trees: *normal form tree*, the *causal tree*, and the *dynamic programming tree*. In this chapter, we focus mainly on the third and the most common type of decision tree – the dynamic programming tree. Such a tree is designed so that, besides providing a useful description of a decision problem, it can also be elaborated with probabilities and utilities and then used as a framework for a particularly simple and transparent method of calculating a Bayes decision rule called *backwards induction* or *rollback*. Such trees enable the DM to identify explicitly a Bayes decision rule even for very inhomogeneous problems. Software is now widely available supporting both the construction of the tree and the rollback calculations illustrated below that enable optimal decision rules to be identified. Because of their expressiveness and versatility, decision trees continue to play a central role in the analysis of discrete decision problems.

Drawing a Decision Tree

The following example is a simplification of the type of decision problem faced by users of a forensic science laboratory (see [1]).

Example 1 The police believe with probability one that a suspect S is guilty. To help convict the suspect, they would like the forensic science service to examine articles of the suspect's clothing for the existence of fibre that matches fibre at the crime scene. The culprit was seen by several witnesses to be wearing a skirt and blouse identical to the one owned by the suspect. If the suspect had sat on a sofa at the crime scene then the probability she picked up a fibre from the sofa that will be found thorough an analysis of the skirt or the blouse are respectively 0.8 and 0.5 where these events are independent. If the suspect has not sat on the sofa the police believe that the probability of finding a matching fibre is zero. On the basis of witness statements the police believe the probability the culprit sat on the sofa is 0.8. The probability they obtain a conviction given they find this match is 0.9 whilst if no such evidence is found then their probability of conviction is 0.1. The police can arrange the examination of the suspect's skirt or blouse or both (in either order). The cost for immediately analyzing both is \$1600. The police could also analyze the skirt alone for \$1200, the blouse for \$800 with these rates also

applying if on analyzing one item of clothing they subsequently decide to analyze the other. Additional costs to the police of going to court are \$2000 but \$0 if they release the suspect without charge. The police's utility $u(x_1, x_2)$ has attributes of cost x_1 and probability of conviction x_2 and has been elicited and found to take the form

$$u(x_1, x_2) = 0.2u_1(x_1) + 0.8x_2 \quad (1)$$

where

$$u_1(x_1) = (4000)^{-1} (4000 - x_1) \quad (2)$$

Such a problem can be usefully represented and the optimal decision discovered using a dynamic programming decision tree. The nodes of the tree, other than those at the tips of its branches, are called *situations* and each situation is either a decision node and represented by $\square$ or a chance node, represented by $\circ$. At a situation, a collection of circumstances can happen. Each edge emanating from a situation is labeled by such a circumstance. If the situation is a decision node, then the edges emanating out of this vertex label the different possible decisions that can be made at that point in time. If the situation is a chance node, then the edges coming out of this vertex label the different possible outcomes that could take place: either subsets of states or observations. We draw the tree with its root (the first situation faced by the DM) on the far left of the page. We then sequentially introduce new situations in an order, consistent with when they are observed or enacted. Conversely, if the value represented by an edge emanating from a chance node $v(c)$ is not known when d_2 is committed to, then $v(c)$ must be introduced after $v(d_2)$ in the tree: i.e., further from the root node.

To illustrate this construction, consider the problem above. The first situation facing the police is a decision. Do they release the suspect immediately or pursue the case in some way? The edge associated with not taking the suspect to court is labeled "release", while the edge associated with not doing this is labeled "pursue". If the police choose not to release the suspect, then, with no new information, they are faced with the choice of how to use the forensic science service (if at all) in the problem above. Here the emanating edges and receiving vertices can

be labeled

$$e_0 = \{\text{go to court now}\}$$

$$e_s = \{\text{pay for the analysis of the skirt}\}$$

$$e_b = \{\text{pay for the analysis of the blouse}\}$$

$$e_2 = \{\text{pay for the analysis of both together}\}$$

So the first part of the tree is given in Figure 1.

Note that we could equally well start with the alternative tree given by Figure 2.

However, the algorithm for calculating a Bayes decision described below always gives the same answer irrespective of the particular choice of the dynamic programming tree [2]. On taking the decision e not to investigate the potential forensic evidence, the situation also labeled by e is whether

Figure 1 Beginning to draw a decision tree

Figure 2 An alternative start to this decision tree

the court subsequently finds the suspect guilty g or innocent i . If they choose to pay for the investigation e_s of the skirt, then the result of this investigation could be positive (+) with a matching fiber being found, or negative (-). So draw two edges out of node e_s to vertices labeled + and -. If a fiber is found on the skirt – i.e., if the police reach situation $(e_s, +)$ then they have their evidence and there is no point in paying for the blouse to be investigated. They therefore need to decide whether to take the suspect to court e or release her $\bar{e}$. On arriving at $(e_s, +, e)$, the court finds the suspect guilty or innocent with the probabilities provided above.

However, if the police learn that there is no fiber on the skirt, i.e., arrive at the situation $(e_s, -)$, then they can decide to release the suspect, take the suspect to court immediately $(e_s, -, e)$, or pay for the investigation of the blouse $e_{s,b}$. On reaching the situation $(e_s, -, e_{s,b})$, a matching fiber is found (+) on the blouse or not found (-), leading by an edge to a situation $(e_s, -, e_{s,b}, +)$ or $(e_s, -, e_{s,b}, -)$. This, in turn, leads to the decision to release ($\bar{e}$), or go to court, i.e., leads to one of the two situations $(e_s, -, e_{s,b}, +, \bar{e})$, $(e_s, -, e_{s,b}, +, e)$ or $(e_s, -, e_{s,b}, -, \bar{e})$, $(e_s, -, e_{s,b}, -, e)$.

Alternatively, the police could choose to investigate the blouse first and then decide on whether to subsequently check the skirt. Proceeding exactly as for the branch starting with e_s but permuting the indices b and s gives us the unfolding of situations after e_b . Finally, on choosing (e_2) to investigate both garments immediately, and depending on whether a fiber is found (+) or not (-) the decision of whether to go to court has to be made. The full tree for this problem is given in Figure 3.

The *leaf nodes* or *terminal nodes* are the ones a maximum distance from the root node: technically the non-root nodes connected to only one other node. For transparency only selected nodes are labelled in the tree above.

Some Comments on Drawing a Tree

1. Even in this small problem, we note that the tree is very bushy. However, since such trees are now mostly drawn electronically, this is not such a problem, because we are then able to zoom in and out of parts of the tree as we draw or examine it.
2. Like the decision table, the tree provides a useful qualitative framework that can be elicited
3. Each terminal vertex (or equivalently each root-to-leaf path) labels a possible unfolding of circumstances as seen by the DM: here, the police. Thus, all possible consequences are represented on the tree, making the description of the problem appreciable to a client. This transparency means that, in practice, the tree is often modified while it is being elicited as the client remembers various possible turns of events not originally articulated. For instance, in the example above, the client might tell you that there is no time to wait for the results of one fiber test and then perform another: so any act that involves $e_{b,s}$ or $e_{s,b}$ is infeasible. This new information is simple to accommodate: we simply erase paths containing these edges. Alternatively, the police may have to follow a protocol that always examined a skirt if a blouse was analyzed. Again this protocol is easy to obey: we simply remove all paths containing these edges. Conversely, as the tree is drawn, other possibilities may come to mind – here, for example, the possibility of forensic analysis of a different piece of evidence. This type of elaboration can be simply incorporated into the tree. The tree gives natural support to the evolutionary dynamics of the modeling process, allowing the client to continue to develop a model until it is requisite [3].
4. The tree can be made simpler by not representing in it those decision rules that are clearly

Figure 3 The full tree for Example 1

always going to be suboptimal. Here, for example, the decision $(e_s, +, \bar{e})$ of paying to investigate the skirt and then, when a fiber is found, to release the suspect clearly wastes the cost of the investigation: just releasing the suspect $\bar{e}$, must obviously be a better option than this. However, some care needs to be exercised when pruning the tree in this way, since it is quite easy to discard decision rules that might actually be good. This is particularly true if you plan to augment your problem to perform a sensitivity analysis. When in doubt, we suggest you keep the rules in and let them be deleted by rollback algorithms described below. However, sometimes, problems are so complicated, it is necessary to simplify the tree. Various formal techniques, using measures of expected value of information, or a normal form analysis can be used to simplify the tree so that only promising decision rules are compared [2, 4]. Alternatively, we can select only a small subset of the possible decision rules that appear reasonably dense in the space of possible decisions and hope that one of these is close to being optimal.

5. Like all Bayesian decision models, the efficacy of the representation is limited by the imagination of the people providing the description of the problem. However, because of the simplicity and the familiarity of the representation of possible events as a path through time, it often oils the imagination, so that the client's understanding of various intricacies of the process increases or becomes more secure as the tree is drawn.
6. Because a dynamic programming tree is drawn primarily to identify promising decisions, not all variables in the problem are necessarily represented in the tree, but only those that influence the consequences in the problem. In the illustrative example, for instance, whether the culprit sat on the sofa is not represented here. Note, however, that it does appear implicitly and is used to evaluate probabilities on the unfolding root-to-leaf paths.

Embellishing the Tree with Quantitative Information

Once the tree is drawn, we can embellish it by appending *terminal utilities* to the leaves of the root-to-leaf paths and probabilities to the edges emanating

from its chance nodes. Thus, for example, consider the root-to-leaf path ending with the leaf $(e_s, +, e)$ and labeling the unfolding that the police chose to check the skirt which was found to have on it a matching fiber that they then go to court. The financial cost x_1 in this case is the cost of the examination plus the other costs of going to court (\$1200 + \$2000) and the probability of a successful conviction is 0.9 so the utility of this consequence is

$$U(x_1, x_2) = 0.2 (4000)^{-1} (4000 - 3200) + 0.8 \times 0.9 = 0.76 \quad (3)$$

The terminal utilities associated with this problem are given in Table 1.

We can add the probabilities that a chance situation develops into an adjacent situation and append these to the edges emanating from each chance node in the tree. Because the elicited probabilities in the problem usually condition in an order consistent with how the client believes things happen rather than condition on the order things are observed, these are often not elicited directly, but often need to be calculated, using the law of total probability

Table 1 Terminal utilities

Leaf	Cost x_1	Conviction probability x_2	Utility
$\bar{e}$	0	0	0.2
e	2000	0.1	0.18
$e_s, +, \bar{e}$	1200	0	0.14
$e_s, +, e$	3200	0.9	0.76
$e_s, -, \bar{e}$	1200	0	0.14
$e_s, -, e$	3200	0.1	0.12
$e_s, -, e_{s,b}, +, \bar{e}$	2000	0	0.1
$e_s, -, e_{s,b}, +, e$	4000	0.9	0.72
$e_s, -, e_{s,b}, -, e$	4000	0.1	0.08
$e_s, -, e_{s,b}, -, \bar{e}$	2000	0	0.1
$e_b, +, \bar{e}$	800	0	0.16
$e_b, +, e$	2800	0.9	0.78
$e_b, -, \bar{e}$	800	0	0.16
$e_b, -, e$	2800	0.1	0.14
$e_b, -, e_{b,s}, +, \bar{e}$	2000	0	0.1
$e_b, -, e_{b,s}, +, e$	4000	0.9	0.72
$e_b, -, e_{b,s}, -, e$	4000	0.1	0.08
$e_b, -, e_{b,s}, -, \bar{e}$	2000	0	0.1
$e_2, -, \bar{e}$	1600	0	0.12
$e_2, -, e$	3600	0.1	0.1
$e_2, -, \bar{e}$	1600	0	0.12
$e_2, +, e$	3600	0.9	0.74

and/or Bayes rule (see **Bayes' Theorem and Updating of Belief**). This is called *preprocessing* in [5]. In the example above, we can calculate the probabilities associated with the chance nodes labeled $(e_s, e_b, e_2, (e_s, -, e_{s,b}), (e_b, -, e_{b,s}))$.

Thus, if E ($\bar{E}$) denotes the event that the culprit sat (did not sit) on the sofa then, by the law of total probability

$$\begin{aligned} P(+|e_s) &= P(+|e_s, E)P(E) + P(+|e_s, \bar{E})P(\bar{E}) \\ &= 0.8 \times 0.8 + 0 \times 0.2 = 0.64 \\ &\Leftrightarrow P(-|e_s) = 0.36 \end{aligned} \quad (4)$$

Notice that the probability on the complementary edge $P(-|e_s) = 1 - P(+|e_s) = 0.36$, so we can quickly derive the probability of no fiber match from the probability of a positive identification. Similarly, if $N(S)$ and $N(B)$ denote respectively, the events that no matching fiber is found on the skirt (blouse) then

$$\begin{aligned} P(+|e_2) &= P(+|e_2, E)P(E) \\ &= \{1 - P(N(S) \cap N(B)|e_2, E)\} P(E) \\ &= \{1 - P(N(S)|e_2, E)P(N(B)|e_2, E)\} P(E) \\ &= \{1 - 0.2 \times 0.5\} \times 0.8 = 0.72 \end{aligned} \quad (5)$$

by independence. More work is needed to calculate the edge probabilities on the longer root-to-leaf paths. For example, consider the probability $P(-|e_s, -, e_{s,b}, -, \bar{e})$. Then, by our assumption of independence, and from the probabilities given above

$$\begin{aligned} P(N(B)|N(S)) &= \frac{P(N(S) \cap N(B))}{P(N(S))} \\ &= \frac{P(N(S) \cap N(B)|E)P(E) + P(N(S) \cap N(B)|\bar{E})P(\bar{E})}{P(N(S))} \\ &= \frac{P(N(S) \cap N(B)|E)P(E) + P(\bar{E})}{P(N(S))} \\ &= \frac{P(N(S)|E)P(N(B)|E)P(E) + P(\bar{E})}{P(N(S))} \\ &= \frac{0.2 \times 0.5 \times 0.8 + 0.2}{0.36} \\ &= 0.778 \end{aligned} \quad (6)$$

Figure 4 The completed tree (1)

Figure 5 The completed tree (2)

The completed trees are given in Figures 4 and 5.

Folding Back a Tree to Find Optimal Strategies

Once the tree is embellished with edge probabilities and terminal utilities, it is straightforward to use it to calculate a Bayes, or expected utility optimizing decision. The solution algorithm follows a simple and self apparent principle. If you know the optimal decision rule(s) for a particular situation, then an optimal strategy requires you to make an optimal decision if you should reach that situation, then an optimal decision now must be one that plans to make one of these optimal decisions, if that situation is reached. It is straightforward to check that any decision satisfying this principle will give you a

Bayes decision rule: i.e., an optimal policy (see e.g. [2, 5]).

To illustrate how this works for a decision problem described by a tree, consider the possibility that the police choose to get the skirt analyzed, do not find a matching fiber, decide then to pay to check the blouse and obtain a positive result. The DM is then in the situation $(e_s, -, e_{s,b}, +)$, and can choose not to go to court (with an expected utility of 0.1) or to go to court (with an expected utility of 0.72). Clearly, when faced with this decision, any rational DM would choose to go to court. So, on observing this sequence of events, we know this is what the DM would do. Thus, provided the DM plans to choose rationally in the future, the expected utility on reaching $(e_s, -, e_{s,b}, +)$ is 0.72. Append this expected utility with the decision node $(e_s, -, e_{s,b}, +)$ and cross out the $\bar{e}$ edge out of this situation: it should never be used. Similarly on observing $(e_s, -, e_{s,b}, -)$, the DM notes that proceeding to go to court has an associated expected utility of 0.08 while releasing the suspect has a value 0.1. So clearly the DM should plan to release the suspect under this contingency. Cross out the edge labeled e and transfer to the decision node $(e_s, -, e_{s,b}, -)$ the expected utility for the release. Do this for all the penultimate decision nodes in the tree: i.e., the decision nodes all of whose edges lead to a calculated expected utility.

Each of these decision nodes has now inherited an associated expected utility. Now consider the chance nodes leading by an edge to these decision nodes. We can assign an expected utility to these nodes because we have calculated the probabilities of proceeding along each of the edges emanating from such a situation. Thus, consider the chance node $(e_s, -, e_{s,b})$. With probability 0.222 the police will obtain a utility 0.72 and with probability 0.778 a utility of 0.1. So using the formula for expectation, the expected utility associated with reaching this chance node – and then subsequently acting optimally – is

$$0.222 \times 0.72 + 0.778 \times 0.1 = 0.238 \quad (7)$$

Append this expected utility to this chance node and repeat this averaging procedure for all such chance nodes whose edges lead to a node whose associated expected utility has been calculated.

Continuing in this way, calculate expected utilities, appending to situations their expected utilities and crossing out any decision edges associated with suboptimal acts. Thus, for the decision node

$(e_s, -)$ we have calculated all expected utilities $\bar{u}$ associated with not going to court $\bar{e}$ ($\bar{u}(\bar{e}) = 0.14$), going to court e with no more analysis ($\bar{u}(e) = 0.14$), and proceeding to check the blouse for fibers $e_{s,b}$ ($\bar{u}(e_{s,b}) = 0.238$). Clearly, choosing the $e_{s,b}$ course is the best one. So transfer this utility to this node and delete the other edges. Since we know we will take to court if we obtain a match on the skirt with utility 0.76, the expected utility associated with e_s is

$$0.64 \times 0.76 + 0.36 \times 0.238 = 0.572 \quad (8)$$

The completed tree is given in Figures 6 and 7. Note that most software will provide such output automatically, using the algorithm described above.

Having proceeded to this point, we can read the Bayes decision rule. Start at the root and read along the undeleted paths to the remaining leaves,

Figure 6 The tree evaluated completely (1)

Figure 7 The tree evaluated completely (2)

translating into English as we go. Thus, in our example, the DM should take the undeleted edge e_s which is to pay for a search of a matching fiber in the skirt. If this is successful, +, the DM immediately takes the case to court. If a matching fiber is not found —, then the DM should pay to check the blouse. If a matching fiber is found on the blouse, the suspect should be taken to court, but if a match is not found, then the suspect should be released. This decision rule is utility maximizing for this problem.

Other Types of Decision Tree

There are two other types of decision trees that need to be mentioned. The first is the *normal form tree* (Figure 8) [2] and derives directly from Savage's description of a decision problem and the decision table (see **Decision Modeling**). The root node is a decision node with outgoing edges labeling each of the (many) decision *rules*. The next situation has outgoing edges labeled by each state of nature $\theta \in \Theta$. All subsequent situations are also chance nodes representing possible outcomes of experiments performed within the decision rule.

Such trees are very bushy, but are often manageable to write down after the first edge. Below is part of a normal form tree following the decision rule $d'(\mathbf{x})$: "Pay for the analysis of the skirt. If a fiber is found then take the suspect to court, otherwise do not." and letting E denote the event that the culprit sat on the sofa.

Note that there will inevitably be much repetition in such trees. However, there is also a computational advantage to normal form trees, since probabilities

typically appear in their natural causal order. They can therefore often be elicited directly and do not need to be calculated through formulae like the law of total probability or Bayes rule, as they were in the dynamic programming tree. This is useful both for transparency and also with respect to a sensitivity analysis where it is the elicited probabilities (and not functions of these) we would like to perturb. The expected utility associated with each decision rule is simple to calculate using the usual formula for expectation. Thus, in the example above,

$$\begin{aligned} \bar{u}(d'(\mathbf{x})) &= 0.8 \times 0.8 \times 0.76 + (0.8 \times 0.2 + 0.2) \\ &\times 0.14 = 0.537 \end{aligned} \quad (9)$$

In this way, we can calculate the expected utility associated with each decision rule. A Bayes rule will then be a decision rule with the highest expected utility.

Such trees are especially useful in understanding which decision rules are optimal for certain prior inputs and how sensitive a Bayes decision is to these probabilities. Thus, for example, we may want to investigate how sensitive the choice of decision rule is to the specification of the probability that the culprit sat on the sofa. It is easy to check that in this problem, for every possible decision rule, $\bar{u}(d'(\mathbf{x}))$ is a linear function of $P(E)$. Ideas of Pareto optimality then allow us to determine which decision rules could be optimal for some value of this probability and which ranges of the probability made which candidate Bayes decisions optimal (see, for example [2, 4]). Often, the number of such candidate decision rules is small. This type of analysis is called a *normal form analysis*.

A second tree, here called a *causal tree* [6] demands that the order of the nodes in the root-to-leaf paths of the tree is consistent with the order in which situations happen in the modeled context. This is often descriptively the most powerful decision tree and can be used for defining and analyzing various causal hypotheses. Such a tree does not necessarily support the direct implementation of backward induction/roll back. One typical root-to-leaf path on the example above can be written as the sequence of labeled edges: the culprit sits on sofa, a detectable fiber is transferred to her skirt, the police decide to analyze the skirt, the police detect the fiber on the skirt, the police take the suspect to court, the court finds the suspect guilty. Because each root-to-leaf path in this tree tries to represent how things happen
